Disorders leading to PRES have in common cerebral injury due to failure of cerebral autoregulation leading to hyperperfusion, or an excessive vascular reactivity in cerebral arterioles. The hallmark clinical entities that most often cause PRES are hypertensive encephalopathy and eclampsia (see Chapter 129). A focal process that shares some features of this condition is cerebral hyperperfusion syndrome occurring after carotid revascularization, although in this entity the radiologic features tend to be limited to one hemisphere. In patients with chronic hemodynamic failure, distal arterioles tend to dilate to reduce cerebral vascular resistance; in clinical scenarios of a sudden increase in cerebral blood flow (CBF), these maximally dilated cerebral arteries may not be able to adapt further to changes in CBF, leading to cerebral edema and hemorrhage. In addition to impaired autoregulation in the face of hypertension and hyperperfusion, in many cases, PRES is also associated with abnormal capillary permeability in the brain and large-vessel proximal vasoconstriction detectable by angiography. Up to 87% of patients with PRES have diffuse vasoconstriction if studied with angiography, hence, PRES and RCVS (discussed later) often overlap and are felt in many cases to share a common pathogenesis. It is notable that many patients with RCVS will not develop PRES and that patients with PRES may not have RCVS. In PRES, there is vasogenic edema that preferentially affects the posterior hemispheres of the brain and the white matter more than the gray matter. Interspersed in this picture are scattered microinfarcts and microhemorrhages. The most severe cases can manifest as massive global cerebral edema with transtentorial herniation or larger infarcts or hemorrhages.

Clinical Features

The clinical syndrome associated with PRES is dependent on the underlying cause, although regardless of underlying etiology, common clinical symptoms include headache, seizures, loss of visual acuity including blindness, nonlocalizing confusion, and somnolence (Table 44.1). The neurologic examination will not reveal localizing findings on the mental status, although cases

TABLE 44.1 Approximate Frequency of Clinical Features of Posterior Reversible Encephalopathy Syndrome

Clinical Feature	Frequency
Hypertension	80%
Consciousness impairment	75%
Seizures	70%
Headaches	40%
Visual abnormalities	30%
Nausea and vomiting	20%

FIGURE 44.1 Magnetic resonance fluid-attenuated inversion recovery image of posterior reversible encephalopathy syndrome on admission **(A)** and 2 weeks after stopping inciting medication **(B)**.

of cortical blindness and Balint syndrome may occur due to involvement of the occipital lobes (Fig. 44.1). Other described findings include visual field cuts, loss of visual acuity, papilledema, and mild hemiparesis. More prominent bulbar and cerebellar symptoms have been described in case series where the pathology is restricted to the brainstem (Fig. 44.2). A larger variety of clinical syndromes, which can be localized anywhere in the cerebral hemisphere, occurs in the context of severe cases with cerebral infarction or hemorrhage.

Diagnosis

Neuroimaging is essential in the diagnosis of this condition, with magnetic resonance imaging (MRI) providing greater clinical information than computed tomography (CT). The "classical" description in this condition is white matter hyperintensities seen on fluid-attenuated inversion recovery (FLAIR) sequences representing vasogenic edema (see Chapter 22). The FLAIR changes have a predilection to occipital lobes and adjacent posterior temporal and parietal regions and are not typically associated with cerebral microhemorrhages, infarction, or involvement of gray matter structures. A hallmark of this condition is that these clinical findings improve with treatment of the underlying condition, along with the cerebral vasogenic edema. Common underlying predisposing conditions include hypertensive emergency/malignant hypertension, eclampsia, and medication toxicity (notably FK-506 in prevention of transplant organ rejection). Table 44.2 describes a variety of underlying etiologies for PRES.

The differential diagnosis of PRES includes conditions, which have a predilection for causing bilateral involvement of the hemispheres, particularly the white matter, or that affect watershed regions between the major vascular territories. These include progressive multifocal leukoencephalopathy, encephalitis, vasculitis, and watershed infarction from cardiac arrest, among others.

Management

Management of PRES begins with a careful review of medications and discontinuation of any potential inciting agent. Management of other PRES-associated causes and complications, such as hypertension, respiratory failure, and seizures will often require the intensive care unit. Control of hypertensive emergency, if present, is an important part of the symptomatic management. The aim is not to normalize the blood pressure but rather to decrease the mean arterial pressure by 10% to 20% within the first 1 hour, followed over the next 23 hours of a reduction by 5% to 10%; by 24 hours, a typical target is less than 160/110 mmHg

FIGURE 44.2 Fluid-attenuated inversion recovery images of posterior reversible encephalopathy syndrome presenting with prominent brainstem involvement **(A-D)**. Nine days later, the lesions had significantly resolved **(E-H)**.

TABLE 44.2 Etiologies of Posterior Reversible Encephalopathy Syndrome

Malignant hypertension	**Biologic agents**
Eclampsia	• Erythropoietin (in end-stage renal disease)
Immunosuppressants	• Immunomodulatory cytokines (interferon-α, interleukin-2)
• Tacrolimus (FK-506)	• Monoclonal antibodies (rituximab, infliximab)
• Cyclosporine A	• Antiangiogenic agents (bevacizumab)
• Mycophenolate mofetil	• Antilymphocyte globulin
Autoimmune disease	• IVIG
• Systemic lupus erythematosus	**Sepsis**
• Polyarteritis nodosa	**Blood transfusion**
• Wegener granulomatosis	**Other agents**
• Systemic sclerosis	• Antiretroviral agents
Chemotherapy drugs	• Linezolid
• Cytarabine	• Cocaine
• Gemcitabine	• Ephedra
• Methotrexate	• IV contrast agents
• Cisplatin	• Carbamazepine
• Carboplatin	

Abbreviations: IV, intravenous; IVIG, intravenous immunoglobulin.

but not significantly lower due to the risk of hypotension. More rapid blood pressure reduction can promote ischemia due to loss of cerebral autoregulation and in more chronically hypertensive patients a shift of the autoregulatory curve. Continuous infusion of intravenous antihypertensive agents is preferred to allow for precise blood pressure control with the most commonly used agents being labetalol or nicardipine; nitrates should be avoided due to the potential venous dilation leading to an increase in intracranial pressure.

Antiepileptic treatment should be initiated on an emergency basis for treatment of clinical or electrographic seizures or status epilepticus. In patients who do not have a neurologic examination that can be readily tracked, continuous electroencephalogram (EEG) is indicated given the high prevalence of nonconvulsive seizures. The management of convulsive and electrographic status epilepticus is covered elsewhere.

Patients with PRES due to eclampsia should also be started on magnesium infusion (1-2 g/h targeting a serum magnesium level of 2.0-3.5 to 4 mmol/L) LEVEL 7.[1] Magnesium infusion is also recommended for any PRES patient with hypomagnesemia.

Outcome

There are few studies describing outcomes among patients who have had PRES. A good outcome is expected in patients who have not sustained cerebral infarction as demonstrated on diffusion weighted imaging, whereas recurrence is rare if the offending agent is removed. Whether patients without structural injury require long-term antiepileptics has not been well established. Most PRES patients are continued on antiepileptics for 6 months, and the risk of future epilepsy is risk stratified based on imaging and EEG.

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME

KEY POINTS

1. RCVS is a common cause of thunderclap headache associated with convexity subarachnoid hemorrhage.
2. Cerebral vasospasm with cerebral infarction may be delayed for up to 2 weeks after the onset of the subarachnoid hemorrhage and is associated with elevated velocities on transcranial Doppler.
3. Treatment of RCVS involved removing the offending medication, and on a case by case basis, intra-arterial or oral verapamil and oral nimodipine; steroids may be harmful.

Introduction

In 2007, the term *reversible cerebral vasoconstriction syndrome* was proposed to encompass several previously described cerebral vascular disorders that mimicked vasculitis: Call-Fleming syndrome, thunderclap headache–associated vasoconstriction, postpartum angiopathy, migraine angiitis, and cerebral vasospasm caused by serotonergic and sympathomimetic drugs.

The RCVS is characterized by a monophasic course of diffuse segmental constriction of cerebral arteries that typically resolved within 3 months. Although the angiographic findings may be similar to primary angiitis of the central nervous system (PACNS) and other vasculitides, RCVS is not associated with inflammation in the cerebral arteries and therefore does not require immunosuppression (or antimicrobials for infectious vasculitis). The cerebrospinal fluid (CSF) does not tend to show the same inflammatory profile as vasculitis, and the clinical course tends to be benign despite similar imaging characteristics.

Epidemiology

Due to the lack of epidemiologic studies, the true incidence of RCVS has not been estimated, although there has been an increased awareness in the neurologic community leading to potentially reported increased rates reflecting ascertainment bias. Overall, RCVS remains a rare complication of all the potential inciting factors with the exception of preeclampsia and eclampsia associated RCVS. Interestingly, it is likely that many of the cases reported previously in the literature as PACNS actually reflected RCVS.

Pathobiology

Other than vasoconstriction and potentially disrupted cerebral autoregulation, there is no known unifying pathologic mechanism that underlies RCVS. An aberrant sympathetic response of cerebral vasculature is one of the preferred hypotheses resulting in an unpredictable and short-lived failure of normal regulation of cerebral arterial tone. This leads to segmental vasoconstriction and vasodilatation in small cerebral vessels, often triggering thunderclap headaches often due to cortical subarachnoid hemorrhage (SAH) or stretching of arterial walls.

The RCVS appears to be triggered by a wide variety of pharmacologic and physical stimuli (**Table 44.3**). Different precipitating factors, including vasoconstrictive drug exposure (serotonergic or adrenergic agents), recreational drugs, and postpartum state are associated with RCVS in around 50% of cases. Head injuries and neurosurgical interventions have also been associated with RCVS.

The PRES occurs in a substantial proportion of patients with RCVS. Hence, a shared pathophysiology between these two overlapping syndromes is highly probable. Severe forms of RCVS are likely to lead to PRES.

Clinical Features

In over 80% of cases, patients present with a sudden onset of single or recurrent thunderclap headaches, oftentimes associated with cortical SAH, which distinguishes RCVS from aneurysmal SAH. Focal neurologic deficits may occur during the original presentation due to cerebral infarction or intracerebral hemorrhage. In patients with isolated cerebral arterial vasoconstriction, cerebral infarction may occur up to 2 weeks after the initial thunderclap headache leading to delayed focal neurologic symptoms. Headaches in RCVS may persist for several weeks after the initial presentation.

Diagnosis

Diagnostic criteria have been proposed for RCVS that encompass clinical, radiographic, and CSF findings. An important aspect of the diagnosis is a comprehensive history of all medications, recreational drugs, and supplements as they can be common triggers for RCVS. Because RCVS can mimic PACNS, differentiation is crucial because management is extremely different (**Table 44.4**). Basic hematologic

TABLE 44.3 Precipitants of Reversible Cerebral Vasoconstriction Syndrome[a]

Vasoactive drugs	Illicit drugs: cocaine, amphetamines, LSD, MDMA (also known as *ecstasy*) Antidepressants: selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors α-Sympathomimetic agents: phenylpropanolamine, pseudoephedrine, ephedrine Other: triptans, ergot alkaloid derivatives, ginseng
Catecholamine-secreting tumors	Pheochromocytoma Bronchial carcinoid tumor
Immunosuppressants or blood products	Intravenous immunoglobulin Tacrolimus Cyclophosphamide Erythropoietin α-Interferon Red blood cell transfusion
Metabolic abnormalities	Hypercalcemia Porphyria Phenytoin intoxication Binge drinking
Neurologic pathologies	Traumatic brain injury Neurosurgical interventions, for example, postcarotid endarterectomy Subdural spinal hematoma Cerebral venous thrombosis CSF hypotension Autonomic dysreflexia/paroxysmal sympathetic hyperactivity
Pregnancy and puerperium	Usually peripartum or postpartum Associated with eclampsia or preeclampsia

Abbreviations: CSF, cerebrospinal fluid; LSD, lysergic acid diethylamide; MDMA, 3,4-methylenedioxymethamphetamine.
[a]Modified from Ducros A. Reversible cerebral vasoconstriction syndrome. *Lancet Neurol*. 2012;11(10):906-917.

and metabolic tests, including erythrocyte sedimentation rate and liver and renal function tests, are typically normal in RCVS. Tests to rule out CNS vasculitis should be performed as delineated in Table 42.3 as well as urine toxicology screens.

A normal CSF profile is typical, although mild abnormalities in the CSF can be present when subarachnoid or intracerebral hemorrhages exist. If the white blood cell count exceeds 10 cells/μL or the protein concentration exceeds 80 mg/dL, analysis of CSF should be repeated after a few weeks to ensure that these abnormalities have normalized. In patients with a typical clinical and radiographic presentation and a well-identified trigger, a lumbar puncture can be postponed.

A significant proportion of patients may have normal parenchymal imaging (either CT or MRI) despite vasoconstriction seen on vascular imaging. Common findings include convexity SAH, intracerebral hemorrhage, and cerebral infarcts.

Digital subtraction angiography is the most sensitive method for demonstrating multifocal segmental vessel constriction, particularly in smaller and distal arteries (Fig. 44.3). Arterial imaging with computed tomography angiogram or magnetic resonance angiogram (MRA) can demonstrate medium- to large-sized arterial vasoconstriction and can be sufficient in cases with typical clinical and parenchymal imaging features without requiring digital subtraction angiography. Findings on angiography may be dynamic, with repeat scans demonstrating resolution of some abnormalities and new vasoconstriction of others. Initial angiography might

TABLE 44.4 Summary of Critical Elements for the Diagnosis of Reversible Cerebral Vasoconstriction Syndrome[a]

A.	Transfemoral angiography or indirect computed tomography angiography or magnetic resonance angiography documenting multifocal segmental cerebral artery vasoconstriction
B.	No evidence for aneurysmal subarachnoid hemorrhage
C.	Normal or near-normal cerebrospinal fluid analysis (protein level <80 mg/dL, leukocytes <10-15/mm^3, and normal glucose level)
D.	Severe, acute headaches with or without additional neurologic signs or symptoms
E.	Monophasic course without new symptoms more than 1 mo after clinical onset
F.	Reversibility of angiographic abnormalities within 12 wk after onset. If death occurs before the follow-up studies are completed, autopsy rules out such conditions as vasculitis, intracranial atherosclerosis, and aneurysmal subarachnoid hemorrhage, which can also manifest with headache and stroke.

[a]Adapted from the International Headache Society criteria for acute reversible cerebral angiopathy and the criteria proposed in 2007 by Calabrese. Headache Classification Subcommittee of the International Headache Society. The international classification of headache disorders. 2nd ed. *Cephalalgia*. 2004;24(suppl 1):1-160; Ducros A. Reversible cerebral vasoconstriction syndrome. *Lancet Neurol*. 2012;11(10):906-917.

be normal if performed very early in the course of the disease, whereas in latter stages, an infusion of intra-arterial verapamil could help determine if vasospasm is present. The onset of headache and cortical SAH may precede the development of vasospasm on vascular imaging. Elevated flow velocities can be demonstrated on transcranial Doppler (TCD) after the initial presentation and may predict risk of subsequent cerebral infarction.

Management

Treatment of RCVS is largely supportive and no specific agents have been examined in the randomized clinical trials. Several agents purported to relieve vasoconstriction have been used in

FIGURE 44.3 Multifocal beading of the cerebral vasculature, characteristic of reversible cerebral vasoconstriction syndrome. (From Neil WP, Dechant V, Urtecho J. Pearls & oy-sters: reversible cerebral vasoconstriction syndrome precipitated by ascent to high altitude. *Neurology*. 2011;76:e7-e9.)

RCVS and reported in case series including *nimodipine*, *verapamil*, and *magnesium sulfate*, although none have clearly reduced the risk of cerebral infarction. Steroids on the other hand do not reduce the risk of RCVS-associated infarction and may actually increase the risk of neurologic complications. Management focuses on discontinuation or avoidance of precipitating agents, blood pressure control, antiepileptic drugs for seizure control, and management of headaches with similar agents used for status migrainosus (except for vasoactive medications such as triptans or dihydroergotamine [D.H.E. 45]). Intra-arterial vasodilators and balloon angioplasty have been used in severe cases with unclear efficacy. Frequent neurologic monitoring is indicated for detecting vasoconstriction-associated cerebral infarction, and although the duration has not been well established, most cerebral infarcts will occur in the first 2 weeks and can be predicted by elevated velocities on TCD.

Outcome

The RCVS is generally considered a monophasic, self-limiting condition with a good long-term prognosis. Headaches usually resolve within 3 weeks, and neurologic complications are rare after 2 weeks. The angiographic and parenchymal findings typically resolve within 3 months. Less than 5% of patients develop fulminant disease with multiple strokes and global cerebral edema. The vast majority of patients make a complete functional recovery. The case fatality rate is less than 1%.

FIBROMUSCULAR DYSPLASIA

KEY POINTS

1. Fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic arteriopathy of medium-sized vessels of unknown cause.
2. The cervicocranial carotid and vertebral arteries are the most common extrarenal site of FMD.
3. The characteristic radiographic appearance of FMD vessels is a "string of beads" reflective of alternating areas of constriction and dilation.
4. Intracranial aneurysms and cervical dissections are the most common manifestations of symptomatic cervicocranial FMD.

Introduction

Fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic arteriopathy of medium-sized vessels of unknown cause. Although it can affect any vascular bed, the renal and cervicocranial carotid and vertebral arteries are most commonly involved.

Epidemiology

Cervicocranial FMD is a rare condition, with one autopsy study citing an overall prevalence of 0.02%. Rates for renovascular FMD are higher, with prevalence estimates of up to 4% shown in several studies. In confirmed FMD cases, renal involvement is generally seen in up to 65% of cases, with cerebrovascular involvement in 25% to 30% of cases. In a series of 1,100 FMD patients, women were twice as frequently affected as men with Caucasians disproportionately affected. The mean age of diagnosis in patients with cerebrovascular involvement is 50 years, older than for renovascular involvement. Approximately 10% of cases are felt to be familial. Diagnosis is frequently delayed, with up to 9 years elapsing from initial symptoms to diagnosis.

Pathobiology

There are three types of FMD, characterized by arterial layer of involvement: intimal fibroplasia, medial dysplasia, and adventitial fibroplasia. Intimal fibroplasia occurs in up to 10% of cases and results from accumulation of abnormal subendothelial mesenchymal cells, which project into the vessel lumen. This commonly results in areas of smooth, focal stenosis or long tubular stenosis. Adventitial fibroplasia, where the fibrous adventitia is replaced by collagen, is very rare.

Medial dysplasia is the most common, with three distinct subtypes recognized: medial fibroplasia, perimedial fibroplasia, and medial hyperplasia. Medial fibroplasia is the most common and accounts for up to 80% of cases.

The main histologic hallmark is disruption of smooth muscle cells, which are replaced by fibroblasts and collagen. There is frequently secondary disruption of the internal elastic lamina, which may lead to aneurysm formation. The alternating areas of medial disruption give rise to the commonly seen "string of beads" radiographic appearance, where areas of stenosis are admixed with dilated areas that are of larger caliber than the original vessel. Perimedial fibroplasia results from abnormal collagen deposition between the media and adventitia, leading to areas of stenosis with preserved internal elastic lamina. Radiographic appearance may be similar to medial fibroplasia, but the "beads" are of smaller diameter than the original vessel.

Although the etiology is unknown, FMD is associated with a variety of diseases including α_1-antitrypsin deficiency, Marfan syndrome, and Alport syndrome.

Clinical Features

Cervicocranial FMD is frequently an incidental finding and rates of neurologic symptoms vary. Neurologic complications mainly arise due to ischemic or hemorrhagic symptoms that result from stenosis, thrombosis, dissection, or aneurysmal formation. Carotid-cavernous fistulas have also been described. Severe stenosis can cause distal hypoperfusion. Thrombotic occlusion of a stenotic vessel or distal embolism can lead to hemispheric ischemic symptoms. An SAH can result from intracranial aneurysm rupture. Spontaneous cervical dissection can also occur, and headache, dizziness, carotidynia, pulsatile tinnitus, and Horner syndrome are all symptoms commonly seen with cervicocranial FMD. Dissection may be more common in Asian populations, whereas "carotid webs" are an increasingly recognized form of intimal FMD in African Americans. Carotid bulb diaphragms also known as *carotid webs* are an atypical form of FMD. The web represents an area of intimal hyperplasia, and it is more commonly seen in African Americans. Thrombus formation at the site of the web is a cause of stroke.

Diagnosis

The gold standard for diagnosis remains catheter-based angiography. Noninvasive imaging modalities such as Doppler ultrasound and MRA may also detect FMD, but because lesions most commonly occur in the middle to distal carotid artery near

FIGURE 44.4 Angiogram of fibromuscular dysplasia in a 43-year-old female patient with multiple transient ischemic attacks. Note the multiple saccular dilatations of the internal carotid artery between the first and second cervical vertebrae.

C1-C2, adequate visualization with Doppler may be limited. Based on the underlying histology, a string of beads appearance due to medial fibroplasia is most commonly seen. Aneurysmal dilatation and areas of smooth tubular stenosis may also be present (Fig. 44.4). When cervicocranial disease is discovered, intracranial vessels should be imaged to evaluate for aneurysms and renal vessels for renovascular disease that may predispose to hypertension. The main differential diagnoses to consider are vasculitis and atherosclerotic disease.

Management

No trial data exist to guide treatment. Antiplatelet therapy is generally used when FMD is diagnosed to prevent thrombotic complications, although some practitioners institute therapy only when symptoms occur. In cases of dissection, a short course of antiplatelet therapy is often used. When intracranial aneurysms are present, treatment is based on size.

Outcome

Although outcome data is limited to case series, in general, the course of cervicocranial FMD is fairly benign. Many patients who are asymptomatic at the time of diagnosis remain so at follow-up several years later. The main cause of long-term morbidity is related to extracranial manifestations.

MOYAMOYA DISEASE

KEY POINTS

1. Moyamoya disease is a chronic, progressive steno-occlusive arteriopathy of unclear etiology.
2. The distal supraclinoid internal carotid artery and/or proximal anterior and middle cerebral arteries are most commonly affected.
3. Ischemia due to hemodynamic failure is the most common presentation of moyamoya disease in children and most adults.
4. Intracerebral hemorrhage occurs in some adult patients and is most common in Asia.
5. Both indirect and direct revascularization can be used to prevent ischemic strokes and hemorrhage.

Introduction

Moyamoya disease (MMD) is a chronic, progressive steno-occlusive arteriopathy of unclear etiology that affects the distal supraclinoid internal carotid artery (ICA) and/or proximal anterior and middle cerebral arteries. Chronic occlusive disease is believed to result in ischemia with subsequent neovascular proliferation of small, fragile, collateral vessels at the base of the brain. It is the hazy, fluffy angiographic appearance of this fine collateral network from which the name derives, as moyamoya means "puff of smoke" in Japanese. An essential distinction is between MMD and moyamoya syndrome, where the latter refers to vessel stenosis and subsequent collateralization owing to a clearly identifiable underlying provoking condition (see Table 44.5 for causes of secondary moyamoya syndrome). The following discussion

TABLE 44.5 Secondary Causes of Moyamoya Disease (Moyamoya Syndrome) and Mimics[a]

Genetic disorders	Sickle cell disease

Fibromuscular dysplasia	

[a]Adapted from Scott MR, Smith ER. Moyamoya disease and moyamoya syndrome. *N Engl J Med*. 2009;360:1226-1237.

focuses on idiopathic/primary MMD, although management may be similar regardless of underlying etiology.

Epidemiology

Worldwide incidence and prevalence data is limited. The MMD was initially described in Japan, and incidence is generally felt to be highest in East Asia. Overall, worldwide incidence appears to be rising, although epidemiologic studies are limited by differences in data collection methods. Ascertainment bias due to increased disease awareness is also possible. Literature originating from East Asia reports incidence rates of 0.54 per 100,000 to 2.3 per 100,000 depending on the country, with higher rates reported in later reports and generally a higher female preponderance. There are far fewer North American and European epidemiologic studies, although the incidence tends to be lower than in East Asia with still a female predominance. A large case series from the Mayo clinic showed higher rates of moyamoya syndrome among women of European descent compared to others, starting in the fourth decade of life and with a significant prevalence of autoimmune diseases (notably Graves and Hashimoto disease and type 1 diabetes mellitus). A bimodal distribution of age of onset is generally demonstrated with a pediatric and adult presentation in Asia, and a predominant adult presentation (after excluding sickle cell disease) MMD is the most common cause of pediatric stroke in Asia. Clustering of MMD within families has been recognized, with rates as high as 15% in studies from Japan, consistent with an autosomal dominant trait with incomplete penetrance. Genetic heterogeneity is demonstrated by at least four documented linked loci; one site is located at 17q25.3, but no culprit gene has been identified.

Pathobiology

The etiology of MMD remains unknown. Histopathologic studies have shown the stenotic vessels to have a severely thickened intima, primarily driven by smooth muscle proliferation, with luminal thrombosis and duplication and tortuosity of the internal elastic lamina frequently demonstrated on autopsy specimens. Signs of vascular inflammation are distinctly absent. Moyamoya vessels, the medium-sized dilated vessels originating from the distal ICA or proximal circle of Willis vessels, form complex networks, which anastomose with distal anterior cerebral artery and/or middle cerebral artery (MCA), with small, fragile, dilated vessels that penetrate the base of the brain. Pathologic evaluation has shown these dilated vessels to either have a very thin wall, prone to microaneurysm formation, or to be thick-walled with significant luminal stenosis and thrombosis.

Based on identification of a familial predisposition of 15% in Asia, recent genetic linkage studies identified the first susceptibility gene for MMD: RNF213 on chromosome 17, with the p.R4810K mutation demonstrating a high prevalence among East Asians. Although the exact etiologic role in MMD remains unknown, RNF213 is known to mediate vascular development in zebrafish, and its role in MMD is under active investigation. Interestingly, the p.R4810K mutation has not been found in European origin populations.

Clinical Features

The main clinical manifestations relate to ischemia in the territory of the stenotic vessel, most often due to hemodynamic flow failure (rather than artery-to-artery embolus) or hemorrhage from the fragile neovascular lenticulostriate vessels. Both intracerebral and SAH can occur. Among adults, hemorrhage is more common in Asia and rarer in North American and European cohorts; hemorrhage is infrequent in pediatric cases. Intracerebral hemorrhage is most common in deep locations and supratentorially and adjacent to dilated penetrating vessels. This is presumably due to either rupture of microaneurysms or simply rupture of the fragile vessel wall in the setting of persistent hemodynamic stress. An SAH may occur due to saccular aneurysm rupture at the circle of Willis frequently affecting the posterior circulation (most commonly the basilar bifurcation) because it is placed under increased stress given its role in providing collateral blood flow. Convexity SAH has also been observed in the setting of dilated pial collaterals, which are subsequently more prone to rupture.

Ischemia is the most common presentation in children and in adults in most studies. Ischemic symptoms are frequently hemispheric, with either a transient or fixed deficit depending on duration of ischemia and are attributable to hemodynamic failure. Some patients may develop ischemic symptoms exclusively in deep hemispheric structures with relative sparing of cortical function. Cerebral infarction due to embolism or in situ thrombosis of a stenotic vessel is uncommon. In children, symptoms have been described as provoked by maneuvers that lead to hyperventilation and thus vasoconstriction, such as crying or inflating a balloon. Exercise-induced symptoms are another possible manifestation of chronic hemodynamic failure.

Other common manifestations of MMD include refractory migraine-like headache, thought to be due to dilation of meningeal and leptomeningeal vessels with subsequent activation of dural nociceptive receptors as well as seizures. Some patients, particularly pediatric, present primarily with cognitive or psychiatric symptoms from hypoperfusion, most commonly when bilateral frontal lobes are involved. Cognitive profiles of children with MMD reveal lower intelligence quotients independently of the incidence of stroke.

Diagnosis

Diagnosis rests on angiographic demonstration of stenosis or occlusion of the bilateral supraclinoid ICAs and/or proximal anterior cerebral artery/MCAs with resulting proliferation of a small, fine network of collateral vessels originating just distal to the site of stenosis. The determination of MMD versus syndrome is incumbent upon exclusion of underlying conditions, which could predispose to the arterial narrowing including large vessel vasculitis or atherosclerosis. Recently, diagnostic guidelines have acknowledged that MRI and MRA can be used in lieu of conventional angiography if bilateral distal ICA stenoses on MRA are accompanied by abnormal vascular networks within the basal ganglia, frequently described as two or more flow voids (Fig. 44.5). In children, if the collateralization is present unilaterally but bilateral ICAs are stenotic, the condition is considered "definite" MMD, but when adults present with unilateral features, they are termed *probable moyamoya disease*. In some case series, up to 50% of patients will start with unilateral involvement, although in fact, many unilateral cases at 5 years of follow-up will demonstrate bilateral involvement. Posterior circulation involvement may be present in up to 10% of patients.

Disease severity on angiography is graded using the Suzuki classification, a scheme with six phases denoting increasing disease progression (Table 44.6). The MMD can progress to any stage without further progression; only a minority of patients progress to stage 6.

In addition to angiographic severity, assessment of hemodynamic status may provide further insight into the clinical severity

FIGURE 44.5 Internal carotid artery angiogram demonstrating moyamoya disease. (From Yamauchi T, Tada M, Houkin K, et al. Linkage of familial moyamoya disease [spontaneous occlusion of the circle of Willis] to chromosome 147q25. *Stroke*. 2000;31:930-935, with permission.)

of MMD in those patients without stroke. Proposed imaging methods include single-photon emission CT (see Chapter 23), CT perfusion (see Chapter 21), and magnetic resonance perfusion. The CT perfusion/magnetic resonance perfusion also allows assessment of vascular reserve by allowing evaluation of cerebral blood volume: As the severity of stenosis progresses, the distal arteries vasodilate, producing an increase in cerebral blood volume. Single-photon emission CT can also be used to assess vascular reserve by measuring changes in CBF before and after administration of acetazolamide, a carbonic anhydrase inhibitor that induces a transient metabolic acidosis in the brain, resulting in vasodilation. Failure to augment CBF in an area of reduced perfusion after acetazolamide implies that the distal vascular territory is already maximally dilated and hence at greater risk for progression to infarction. TCD ultrasonography (see Chapter 24) can also measure cerebrovascular reserve by comparing flow velocities before and after induced hypercapnia after inhalation of 5% carbon dioxide via face mask. Failure to augment CBF velocity by 5% implies a state of maximal vasodilation and greater risk. Many centers will use degree of impaired vascular reserve to both risk stratify patients prior to surgery who have not had stroke. Novel measures of CBF, including arterial spin labeling and blood oxygen level–dependent MRI, have been proposed for measuring CBF but are not widely available.

TABLE 44.6 Suzuki Scale for Severity of Moyamoya Disease[a]

	Suzuki Stage	Angiographic Description
1	Narrowing of distal carotid	No other angiographic abnormalities aside from carotid narrowing
2	Initiation of the moyamoya	First signs of fine collateral networks become apparent.
3	Intensification of the moyamoya	Collaterals become more pronounced; MCA and ACA may start to become obscured.
4	Minimization of the moyamoya	First signs of ECA collaterals are apparent; moyamoya collaterals start to thin.
5	Reduction of the moyamoya	Moyamoya collaterals further regress; carotid occlusion progresses proximally.
6	Disappearance of the moyamoya	Only intracranial blood flow is via collaterals from the ECA; no angiographic evidence of distal carotid or moyamoya collaterals at the base of the brain

Abbreviations: ACA, anterior cerebral artery; ECA, external carotid artery; MCA, middle cerebral artery.

[a]Adapted from Suzuki J, Takaku A. Cerebrovascular "moyamoya" disease. Disease showing abnormal net-like vessels in base of brain. *Arch Neurol*. 1969;20:288-299.

Management

There are no randomized clinical trials to guide management in MMD patients who are asymptomatic or present with ischemic symptoms. The Japan Adult Moyamoya trial, randomized patients who presented with intracerebral hemorrhage to surgery versus conservative management within 1 year of presentation. The recurrent hemorrhage rate was 11.9% in the surgical group compared with 31.6% in the conservative group (an annualized risk of 2.7% vs 7.6% per year; $P = .04$) LEVEL 2[2]; patients with a posterior predominant pattern of moyamoya-like vessels had the maximal benefits of bypass surgery.

Among patients with ischemic symptoms, treatment recommendations are based on case series and expert opinion. The goal of surgical approaches is to augment CBF, thereby hoping to reduce the risk of ischemic stroke and the strain on dilated deep moyamoya-type vessels, which may be prone to hemorrhage. Bypass surgery is generally performed in patients who have had ischemic symptoms, whereas the management of asymptomatic patients is generally based on risk stratification using imaging to quantify CBF or vascular reserve. There are multiple revascularization strategies, generally divided into direct and indirect approaches. No randomized controlled trials have directly compared these techniques, although the direct approach was used in the Japan Adult Moyamoya trial.

The direct approach is an anastomosis between the intracranial and extracranial circulation, which is most commonly achieved by connecting the superficial temporal artery to a branch of the MCA on the cortical surface. With this procedure, revascularization is immediate. Downsides include an increased risk of perioperative stroke or hemorrhage and the frequent occurrence (up to 25% in some studies) of the cerebral hyperperfusion syndrome, owing to the immediate revascularization in the setting of altered hemodynamics. The main symptoms of this syndrome include hemorrhage, seizures, and focal neurologic deficits from vasogenic cerebral edema.

There are several indirect approaches possible, although only encephaloduroarteriosynangiosis is widely used. In the encephaloduroarteriosynangiosis procedure, the superficial

temporal artery (most commonly), is placed on the cortical surface through a dural defect, sometimes with removal of intervening arachnoid (a modification termed *pial synangiosis*). Both of these techniques rely on the induced angiogenesis that naturally occurs between the underlying ischemic cortex and the apposed tissue or vessel. A third procedure is burr hole placement (with stripping of the underlying dura) in the vicinity of ischemic cortex, whereby scalp vessels grow through the burr holes to form collaterals with vessels on the cortical surface. The main complication from the indirect bypass is that augmentation of CBF may take more than 6 weeks to occur. Indirect bypass is more commonly performed in children due in part to direct bypass being more technically challenging. Many centers use a direct and indirect combined approach in adults. The optimal approach in adults is often dictated by donor vessel morphology and characteristics, surgical expertise, and patient preference.

Medical management of MMD has not been formally evaluated in clinical trials, although aspirin 81 mg is commonly prescribed in patients with ischemic symptoms. Anticoagulation is generally avoided given the attendant increased risk of hemorrhage on the setting of fragile vessels.

Outcome

Adults are generally felt to display less progression of proximal occlusion than children with lower recurrent stroke rates. Much of the data on progression in adults is from Japan, where a 5-year rate of progression of proximal stenosis as high as 20% has been shown in the affected vessel. Other studies have shown recurrent ipsilateral stroke rates over 5 years to be as high 65% in the absence of surgery. Female sex is generally the main identified risk factor for disease progression. Even in asymptomatic patients, disease activity is apparent, as seen from a Japanese study where 20% of asymptomatic patients had imaging evidence of infarction, whereas 40% had evidence of impaired cerebral hemodynamics. The annual rate of stroke in this asymptomatic population was 3.2%.

BINSWANGER DISEASE

KEY POINTS

1. Binswanger Disease, also known as ischemic leukoencephalopathy, is a form of incomplete white matter infarction due to small vessel disease.
2. Clinical features include dementia with frontal lobe dysfunction, parkinsonism, and gait disorder.

Introduction

Binswanger disease (BD) refers to a progressive subcortical dementia with white matter degeneration of small-vessel etiology also known as *subcortical arteriosclerotic leukoencephalopathy*. It is not a well-defined disease entity, and in fact, the clinical picture in BD is similar to the subcortical dementia seen in other small-vessel angiopathies, for example, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), which is discussed later in this chapter. In general, the term *Binswanger disease* is appropriately used when subcortical dementia is present in the setting of vascular risk factors with evidence of extensive deep and periventricular ischemic leukoencephalopathy on neuroimaging without an alternative explanatory cause.

Epidemiology

The BD can be considered a subset of vascular dementia (VaD) (see Chapter 54). Given the extensive overlap between cerebrovascular disease and Alzheimer disease and other dementing pathologies, clinical diagnosis of "pure" VaD is fraught with challenges and prevalence estimates are highly variable. Estimating the true prevalence of BD within the context of VaD subtypes is therefore challenging. Although exact numbers are not known, BD in its classical form likely accounts for a small portion of these "pure" VaD cases.

Pathobiology

The general pathologic picture is one of roughly symmetric degeneration of central white matter with myelin pallor and multiple lacunes. The term *incomplete white matter infarction* has been used to describe the pathology of BD. The degree of demyelination is heterogeneous with some areas demonstrating extensive demyelination and gliosis admixed with relatively normal-appearing white matter. Axonal loss is variable, there is no inflammatory cell infiltrate, and cortical atrophy is minimal, if not wholly absent. Although the arcuate fibers and anterior commissure are usually spared, central white matter from the periventricular region to the centrum semiovale, extending from frontal to occipital lobes, is involved to varying degrees. In addition to frequent lacunes, other hallmarks include dilated perivascular spaces, so-called état criblé, and moderately enlarged lateral and third ventricles. The vascular hallmarks are small, penetrating vessels with hyalinized, thickened walls with focal fibrinoid necrosis, notably without occlusion. Generally, there is some degree of atherosclerosis in large, proximal intracerebral arteries. Interestingly, perfusion studies have shown the areas of white matter hyperintensities to have lower CBF, suggesting chronic hypoperfusion and ischemic damage due to the small-vessel changes may be the pathophysiologic mechanism of the white matter degeneration.

Clinical Features

The clinical manifestations of BD owe mainly to the disruption of white matter tracts interconnecting primary processing areas of the brain, theorized in particular to those specifically subserving the frontal cortices. Main signs include those that tend to localize to the frontal lobe, including slowed information processing, memory disturbances, and visuospatial deficits and executive dysfunction; the latter includes impaired initiation, planning, and goal-directed activity. Behavioral disturbances are frequent. Varying degrees of pyramidal and extrapyramidal dysfunction may be present in addition to pseudobulbar signs, parkinsonism, and gait abnormalities. Focal neurologic deficits may be present at the onset or during the disease course, owing to acute lacunar infarction.

Diagnosis

No consensus guidelines exist for the diagnosis for BD. In general, the diagnosis is made when subcortical dementia is found in the presence of vascular risk factors, notably hypertension, with neuroimaging evidence of white matter disease. Other causes of leukoencephalopathy such as acute disseminated encephalomyelitis (ADEM) or progressive multifocal leukoencephalopathy must be absent. In general, patients with a known small-vessel

arteriopathy and associated dementia, such as CADASIL, are not considered under the umbrella term of BD.

The white matter degeneration is best seen on MRI but is also present on CT where confluent, symmetric hypodense areas throughout the central white matter are apparent. On MRI, areas of white matter degeneration appear bright on T2 (white matter hyperintensities) and are best seen on FLAIR sequences where CSF is suppressed. The lesions are generally large and rather than being isolated to the immediate periventricular region, extend throughout the corona radiata and centrum semiovale. Scattered lacunes are frequently seen, both throughout the white and deep gray matter.

Management

Given most patients with BD have evidence of lacunar infarcts, treatment is directed at secondary stroke prevention, that is, modification of vascular risk factors and introduction of antiplatelets and statins. Control of hypertension is essential, in addition to aggressive diabetes management and smoking cessation. There is no evidence that hypertension control leads to reversal of white matter changes. Supportive care for patients with severe cognitive impairment is often necessary.

Outcome

In one series of clinicopathologically confirmed cases, clinical course took one of three patterns: gradual progression punctuated by acute focal deficits, gradual worsening not punctuated by acute focal deficits, and multiple acute focal deficits without progression.

SUSAC SYNDROME

KEY POINTS

1. Susac syndrome is an autoimmune microangiopathic endotheliopathy.
2. Encephalopathy, branch retinal artery occlusion, and hearing loss represent the clinical triad of Susac syndrome.
3. Characteristic radiographic findings include small white matter lesions in the cerebral hemispheres with prominent corpus callosal involvement. Callosal lesions are centrally located and frequently have a "snowball appearance."
4. Treatment is directed at immunosuppression.

Introduction

Susac syndrome comprises a triad of encephalopathy, branch retinal artery occlusion (BRAO), and hearing loss. It is thought to be an autoimmune microangiopathic endotheliopathy that affects brain, retina, and cochlea. The disease, which was first described in 1977 by John O. Susac after he encountered two young women with personality changes, including paranoia and hostile behavior, hearing loss, and visual disturbances, is also termed *retinocochleocerebral vasculopathy* and can be frequently misdiagnosed initially as multiple sclerosis (MS) or ADEM.

Epidemiology

Susac syndrome typically begins in the third or fourth decade but may occur during childhood or after age 70 years. There is 3:1 female predominance but no racial predilection. The true incidence and prevalence of the disease are unknown. Fewer than 1,000 cases have been reported but diagnostic confusion abounds and the condition is likely underdiagnosed.

Pathobiology

Susac syndrome is thought to be an immune-mediated endotheliopathy of unknown etiology. Antiendothelial cell antibodies either play a pathogenic role or arise from endothelial damage caused by other immune mechanisms. Histopathologic examination of brain biopsy samples usually reveals microinfarcts in the cerebral cortex and white matter. Areas of demyelination along with axonal and neuronal damage are also seen. Pauci-inflammatory endothelial cell injury in small arterioles, capillaries, and venules is observed.

Muscle biopsy in patients with Susac syndrome shows abnormal endothelial cells, some swollen to the point of occluding small arterioles. Muscle inflammation is subclinical, unlike dermatomyositis, although the pathology is virtually identical, including endothelial cell degeneration and necrosis as well as thickening, reduplication, and lamellation of the basement membrane.

Clinical Features

Encephalopathy may be manifested by psychiatric symptoms, confusion, memory loss, or simply dulling of cognitive function. The BRAO, which may occur before, during, or after the encephalopathy, may cause a scotoma or photopsia. Migrainous headaches often precede other symptoms, and the association with visual symptoms may be misleading. Hearing loss may be difficult to assess, depending on the degree of encephalopathy. It frequently affects the lower tones first, which implies microinfarction of the cochlear apex, a particularly territory. The speed and severity of hearing loss varies from profound and precipitous, with loss of hearing in one ear and the other days to weeks thereafter, to slow and insidious or fluctuating as in Ménière disease. Hearing loss may be accompanied by nausea, vertigo, tinnitus, or gait ataxia.

Diagnosis

Diagnosis requires a high index of suspicion because it is uncommon for the entire clinical triad to be present at the time of the first encounter with a physician. Furthermore, encephalopathic patients may not complain of hearing loss or visual problems. Brain MRI, dilated funduscopic examination, and retinal fluorescein angiography are the most useful diagnostic tests.

Brain MRI reveals multiple small (typically 1-7 mm) white matter lesions in the cerebral hemispheres. The corpus callosum is involved in 88% to 100% of patients (Fig. 44.6). The callosal lesions that occur with acute encephalopathy are centrally located and have a "snowball" appearance. Basal ganglia, thalamic, brainstem, cerebellar, and gadolinium-enhancing lesions are common. Leptomeningeal enhancement is occasionally observed. Arteriography is typically normal because the affected arterioles are too small to be seen in angiography.

FIGURE 44.6 Susac syndrome findings on magnetic resonance imaging. **A:** Axial fluid-attenuated inversion recovery image shows nonspecific lesions in the cerebral hemispheres. Sagittal fluid-attenuated inversion recovery **(B)** and T1-weighted **(C)** images show the characteristic central "snowball lesions" and "punched out holes," respectively.

Although the MRI findings may lead to an incorrect diagnosis of MS or ADEM, the morphology and central location of the acute callosal lesions and their evolution into hypointense holes on T1-weighted imaging are characteristic findings in Susac syndrome and atypical of MS lesions, which are smaller and involve the callosal-septal interface.

Dilated funduscopic examination and retinal fluorescein angiography may reveal retinal infarcts and BRAO (**Fig. 44.7**). Audiometry may detect sensorineural hearing loss. Examination of the CSF during the acute encephalopathy typically reveals a mild lymphocytic pleocytosis. The protein content is often more than 100 mg/dL, an uncommon finding in MS. However, the occasional presence of oligoclonal bands or an elevated immunoglobulin G index may lead to further diagnostic confusion.

Management

There have been no controlled therapeutic trials in Susac syndrome, but many different approaches have been explored. Treatment recommendations are largely based on case series. Although the disease often enters spontaneous remission, treatment is recommended to try to prevent irreversible disability.

Prednisone monotherapy, pulses of methylprednisolone, or a combination of corticosteroids and intravenous immunoglobulin appears to be beneficial in some patients. More severe cases may respond to *cyclophosphamide* or *mycophenolate* mofetil. Plasma exchange has been used in refractory cases. The use of *rituximab* in dermatomyositis, a humorally mediated autoimmune vasculopathy that shares immunopathogenic features with Susac syndrome, has increased the use of B-cell depletion as a treatment strategy for Susac syndrome. Low-dose aspirin therapy is often added in attempt to forestall microinfarcts. Although aggressive treatment is often indicated, the disease is often self-limited and may remit spontaneously after several years, so tapering of immunotherapy should be attempted judiciously.

Outcome

Three major clinical courses have been described: monocyclic, polycyclic, and chronic continuous. Most patients with symptomatic encephalopathy follow a monocyclic course in which the disease remits spontaneously after 1 to 2 years and does not return. The polycyclic course includes variable periods of remission separating disease activity and may persist for many years.

FIGURE 44.7 **Left:** Retinal abnormalities in Susac syndrome demonstrating hyperfluorescence of the arteriolar walls *(arrowheads)*. **Right:** Retinography of the left eye shows retinal infarct *(arrow)*. (Images courtesy of Zachary Grinspan, MD.)

The chronic continuous syndrome shows variations in severity of symptoms but no clear remissions, even though a slow remission may eventually occur. Case reviews suggest that those with prominent encephalopathy are more likely to have a monocyclic course, whereas those with BRAO and hearing loss may be more likely to develop prolonged polycyclic disease.

The disease usually lasts 2 to 4 years with the chronic continuous course being the least common form of the illness. Although 50% of patients are able to lead a basically normal life, most are left with varying degrees of bilateral hearing loss, and 35% to 50% have residual cognitive dysfunction, which prevents some from returning to work. Asymptomatic visual field defects are much more common than symptomatic visual loss. Treatment with immunosuppressive chemotherapy may result in infertility.

SNEDDON SYNDROME

KEY POINTS

1. Sneddon syndrome is the combination of livedo reticularis and ischemic stroke.
2. Sneddon syndrome can occur in the presence of antiphospholipid antibodies, but many cases are seronegative.

Introduction

Sneddon syndrome refers to the dyad of livedo reticularis (LR), a lacy erythematous or purplish rash on the anterior legs, and ischemic stroke (Fig. 44.8). The exact underlying pathophysiology remains unknown and whether this entity is distinct from, or lies on a spectrum with, the antiphospholipid antibody syndrome remains to be clarified.

Epidemiology

Two forms of Sneddon syndrome are generally recognized: those associated with the presence of antiphospholipid antibodies and those that are not (seronegative cases). This is a rare disease, with the overall annual incidence estimated at 4 per million and with women predominantly affected. In general, first clinical stroke is evident by the mid-40s.

Pathobiology

Two forms of LR are recognized: "physiologic" LR or cutis marmorata, which occurs in the setting of cold temperatures and disappears when the affected limb is warmed, and "secondary" LR due to an underlying condition. In Sneddon syndrome, subcutaneous arteriolar occlusion leads to decreased oxygenation of venous blood that causes LR, generally present over a large area. The trunk and limbs are usually involved, with the violaceous rings appearing irregular and broken.

Pathologic series of skin biopsy specimens of seronegative Sneddon syndrome patients have shown that it is the small- to medium-sized arteries at the dermis–subcutaneous border that are affected. These vessels undergo four stages of involvement. Initially, there is endothelial disruption and lymphocyte infiltration, which is followed by partial vascular occlusion by stimulated monocytes that trap erythrocytes and fibrin, associated with a perivascular lymphohistiocytic infiltrate. Later stages are characterized by reorganization of this plug associated with subendothelial proliferation of smooth muscle cells and resolution of the perivascular infiltrate. The final stage is characterized by proliferation of fibroblasts and collagen, where completely occluded, shrunken vessels are apparent without inflammatory infiltrate. Following the discovery of an initial inflammatory vasculopathy, the presence of antiendothelial antibodies has been found in up to 35% of patients; whether they play a pathophysiologic role remains uncertain.

Unlike skin vessels, pathologic studies of cerebral vessels are limited. Stroke most commonly affects the cortex and subcortical white matter, with some series showing frequent small, multifocal ischemic lesions within the deep white matter, a nonspecific finding that is seen in many disorders affecting small arteries.

FIGURE 44.8 A 62-year-old man with Sneddon Syndrome. He presented with one week of progressive confusion culminating in a fall. On exam he was delirious but non-focal and could only state his name. Brain diffusion weighted imaging **(left)** revealed an acute left posterior cerebral artery infarct and multiple other small infarcts throughout both hemispheres. The day after the MRI extensive livedo reticularis **(right)** developed on his abdomen and lower extremities. (Images courtesy Dr. Stephan A. Mayer.)

Clinical Features

In general, the first manifestations are frequently nonspecific neurologic symptoms such as dizziness and headache. These are followed by LR, which in most cases is followed by stroke, although the two can present simultaneously. On average, symptoms evolve over 9 years. Patients seronegative for antiphospholipid antibodies generally have a wider area of LR and are less likely to have seizures compared to patients with antiphospholipid antibodies. Seropositive patients are more likely to have thrombocytopenia, in keeping with coexistent SLE and other autoimmune disease. Studies showing differences between seronegative and positive patients are however inconsistent.

Multiple MRI patterns in patients have been described including cortical-subcortical infarcts, FLAIR lesions in the deep periventricular white matter, and scattered punctate subcortical T2 hyperintensities. Although the majority of lesions are supratentorial, infratentorial and basal ganglia lesions are less frequent. None of these imaging findings are specific.

Some studies have also shown an increased incidence of hypertension and cardiac valvular abnormalities (thickening and calcification) in keeping with comorbid autoimmune disease.

Diagnosis

Diagnosis is made by the presence of skin biopsy–confirmed LR with the aforementioned pathologic features in the presence of focal neurologic deficit and imaging-confirmed cerebral infarction. Other conditions associated with LR should be ruled out, namely systemic lupus erythematosus (SLE) and polyarteritis nodosa. The presence of antiphospholipid antibodies is not essential for the diagnosis, as up to 60% of cases are considered seronegative.

Management

Seronegative patients are generally treated with antiplatelet agents such as aspirin 325 mg daily, whereas seropositive patients are anticoagulated with warfarin (target international normalized ratio between 2.0 and 3.0), along with current antiphospholipid syndrome (APS) guidelines. Immunosuppressive regimens may be used for coexistent autoimmune disease.

Outcome

Given its low incidence, large longitudinal studies are lacking, which make accurate predictions about outcome challenging.

MARANTIC ENDOCARDITIS

KEY POINTS

1. Nonbacterial thrombotic endocarditis or marantic endocarditis refers to sterile valvular vegetations.
2. Nonbacterial thrombotic endocarditis is most commonly seen in malignancy and systemic lupus erythematosus.
3. Ischemic stroke from vegetation embolization is the most common manifestation.
4. Treatment is generally with anticoagulation; rarely valve surgery is needed.

Introduction

Nonbacterial thrombotic endocarditis (NBTE) refers to sterile valvular vegetations made up of fibrin and platelets, which are found in association with many underlying conditions. Perhaps the most prominent association is with malignancy, where NBTE is termed *marantic* (or "wasted") *endocarditis*, and SLE, where the verrucous vegetations are termed *Libman-Sacks endocarditis* (LSE). The NBTE can also be found in primary APS and is increasingly recognized in a host of other systemic illnesses including sepsis, advanced AIDS, cirrhosis, and extensive burns. It has been hypothesized that hypercoagulability is a common link.

Epidemiology

The most common underlying tumors include mucin-producing adenocarcinomas of the colon, pancreas, ovary, and lung in addition to hematologic malignancies. Autopsy studies have put the incidence of NBTE in the general population at 1% with studies of SLE patients showing rates upward of 30% and as high as 19% among cancer patients, although other series indicate lower rates among cancer patients. Specific features of SLE that predispose to LSE have not been consistent with some studies showing an increased risk in the presence of antiphospholipid antibodies, whereas others have not confirmed this association.

Pathobiology

Despite the underlying cause, the pathology is generally the same: superficial bland vegetations affixed to a valve with preserved underlying architecture. The vegetations generally consist of a fibrin core with aggregated platelets, without any demonstrable evidence of infectious organisms or inflammatory reaction. Vegetations are generally found on left-sided valves, with the mitral valve most commonly affected. Vegetations have a predilection for the atrial side of the mitral valve and ventricular side of the aortic valve and are generally at the contact margins of the valve leaflets, perhaps due to the highest turbulence of blood at these locations with resulting microtrauma to the underlying valve. An underlying immune-mediated destructive process has also been hypothesized in addition to an underlying hypercoagulable state. The NBTE vegetations span a range of sizes, from submillimeter to over 1 cm, with the lesions generally consisting of single or multiple mobile verrucae. It is thought that the lack of inflammatory reaction and attendant cellular organization makes these lesions particularly friable.

Although the underlying valve architecture is generally preserved in NBTE, one large echocardiographic study did find that a majority of patients had some degree of valvular dysfunction, most commonly regurgitation. Mitral and aortic valves were also diffusely thickened, demonstrating frequent calcification of the mitral valve annulus and chordae.

Clinical Features

Although NBTE rarely causes hemodynamically significant valvular dysfunction, the consequence of importance is systemic embolism, of which stroke is the most clinically apparent. In fact, it has been estimated that up to one-third of patients with NBTE have evidence of thromboembolic ischemic stroke, with rates as high as 55% noted in autopsy studies of cancer patients and between 10% and 20% in patients with SLE. Studies on the brain MRI findings of NBTE patients show that the majority of cases have evidence of

numerous small- and medium-sized infarcts in multiple vascular territories. This was in contrast to infective endocarditis patients, where infarcts along with microhemorrhages or hemorrhages (parenchymal and subarachnoid) are seen.

Diagnosis

Because the lesions are generally smaller and not associated with underlying valvular dysfunction, cardiac murmurs are infrequent. Identifying NBTE is often more difficult than infective endocarditis and requires a high index of clinical suspicion, such as multiple infarcts in the setting of systemic malignancy or autoimmune disease in the absence of other explanations. Transesophageal echocardiography (TEE) is often needed, as the small size makes transthoracic echocardiography evaluation insensitive. Indeed, one series demonstrated over twice the diagnostic yield of TEE compared with transthoracic echocardiography in cancer patients with NBTE; TEE may nonetheless show no clear vegetations and NBTE may only be present on autopsy. TCD with microembolic signal detection over 30 minutes many demonstrate evidence of high-intensity transients consistent with microembolic, but the yield remains unknown. Diagnosis rests on excluding an underlying infection; thus, serial blood cultures in addition to a thorough systemic infectious evaluation is necessary. The distinction from culture-negative infective endocarditis may be particularly challenging because patients with malignancy and autoimmune disease often present with fever. In general, it is reasonable to consider NBTE in embolic stroke of unknown source patients with embolic-appearing infarcts when there is a concern for an underlying malignancy or rheumatologic disease.

Management

Although no trial data exists on treatment for NBTE, anticoagulation is generally recommended in those with marantic endocarditis and evidence of thromboembolic stroke. Heparinoids are preferred to warfarin given the superiority of the former in preventing venous thromboembolism in cancer patients. When NBTE is identified in patients with primary or secondary APS with evidence of stroke, anticoagulation with warfarin is generally recommended per APS treatment guidelines. The case of SLE with LSE is less clear, and in general, antiplatelet agents are recommended if there is no evidence of thromboembolism, with anticoagulation considered if strokes occur. No data exists on improvement in LSE lesions with immunologic therapy.

An additional concern is the potential for NBTE lesions to get secondarily infected; thus, antibiotic prophylaxis may be warranted in certain situations, for example, prior to high-risk dental procedures or surgery. Although rare, in severe cases with multiple strokes refractory to anticoagulation, surgical mitral valve replacement has been used.

Outcome

The outcome of NBTE generally depends on the underlying disease process. Echocardiography-based studies of patients with LSE have shown that during follow-up between 1 and 5 years, vegetations persisted, regressed, or appeared, making the course highly unpredictable. In marantic endocarditis, prognosis often depends on the underlying malignancy, with anticoagulation somewhat effective in preventing recurrent stroke, although refractory cases have been reported.

CEREBRAL AUTOSOMAL DOMINANT ARTERIOPATHY WITH SUBCORTICAL INFARCTS AND LEUKOENCEPHALOPATHY

KEY POINTS

1. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is autosomal dominant and presents with multiple strokes despite adequate medical therapy in the subcortical region.
2. Progressive cognitive impairment is seen in CADASIL even without clinically overt infarcts.
3. Characteristic imaging includes fluid-attenuated inversion recovery hyperintensities in the external capsule and anterior temporal lobe, cortical atrophy, and multiple cerebral microbleeds.
4. Commercially available CADASIL tests cover the most frequent mutations but do not capture several de novo or founder mutations and whole-exome or whole-genome testing may be needed.

Introduction

The CADASIL is one of the few single-gene disorders that causes stroke. The median age of the first stroke is 50 years, although the strokes may occur as early as 19 years of age. Common stroke risk factors, such as hypertension and diabetes mellitus, are conspicuously absent. The MRI findings include a widespread leukoencephalopathy, and the findings are virtually pathognomonic when involvement of the anterior temporal lobes and external capsule is seen. Subcortical cerebral microbleeds are also commonly present. A phenotypic variant of CADASIL has been identified by familial clustering of hemiplegic migraine and labeled CADASILM ("M" for migraine.)

Epidemiology

Minimum prevalence has been estimated at 1.98/100,000 adults from a population-based study in Scotland. Due to underdiagnosis, this is likely an underestimate of the true prevalence.

Pathobiology

The CADASIL is a protein elimination failure angiopathy, similar to amyloid angiopathy (see Chapter 39). The genetic defect is a mutation on chromosome 19p, in the *NOTCH3* gene, a highly conserved gene regulating development. The protein is a transmembrane receptor involved in intercellular communication, and it is found on vascular smooth muscle cells. The mechanism by which the smooth muscle cell pathology leads to vasculopathy and stroke remains uncertain, but it does not appear to be a thrombotic disorder.

Clinical Features

Patients present with multiple subcortical infarcts, progressive dementia, and gait disorder. Migraine headaches especially with aura are common. Psychiatric manifestations such as depression and psychosis are frequently seen.

Diagnosis

Diagnosis is made by genetic testing, which can detect 70% of the clustering mutations causing the disease, or skin biopsy, in which the presence of granular osmiophilic material between smooth muscle cells and the basement membrane or immunostaining for the Notch3 protein is seen.

Management

Apart from antiplatelet therapy with aspirin, clopidogrel, or a similar agent, there is no known treatment. Control of blood pressure when comorbid hypertension is present and smoking cessation are essential to prevent additional subcortical injury. Genetic counseling about disease risk for offspring is an essential component of care.

Outcome

The mean survival time is 20 years from onset of symptoms.

45 Primary and Secondary Stroke Prevention

Charles C. Esenwa and Mitchell S. V. Elkind

KEY POINTS

1. Primordial stroke prevention measures target community-level stroke risk factors and aim to improve population-level cardiovascular health through broad healthy living campaigns.
2. In general, the most important individualized risk factor for stroke is hypertension, which accounts for at least one-third of all strokes.
3. After an ischemic stroke has occurred, the goal is to minimize disability and prevent recurrent events using an approach that is specific to the stroke subtype and personalized risk factors.
4. The stroke subtypes of large artery atherosclerosis, cardiogenic, and small-vessel disease require differing prevention strategies.
5. Anticoagulation is the main stroke prevention strategy in patients with atrial fibrillation.
6. Carotid endarterectomy or carotid artery stenting is recommended for patients with ischemic stroke in the territory of a severely stenotic internal carotid artery.
7. Patients with all ischemic stroke subtypes require a multipronged approach aimed at controlling modifiable stroke risk factors such as hypertension, diabetes mellitus, hypercholesterolemia, and tobacco use.

INTRODUCTION

Prevention of stroke can be divided into three types: (1) primordial prevention, which focuses on improving community-wide health behaviors, such as diet, exercise, and smoking; (2) primary prevention, which attempts to mitigate an individual's stroke risk factors; and (3) secondary prevention, which targets risk of stroke recurrence in those who have already suffered a stroke or transient ischemic attack (TIA).

Risk factors are generally classified as either nonmodifiable or modifiable. Nonmodifiable risk factors, although they cannot be altered, remain important in quantifying a patient's future risk of stroke. Examples include age, sex, family history, ethnicity, and race. Modifiable risk factors allow for intervention to decrease future risk of stroke.

Primordial prevention deals with population-level strategies aimed at reducing the development of cardiovascular disease and specifically stroke. Primary and secondary prevention measures should be individualized and require a careful history and tailored diagnostic evaluation to stratify stroke risk and guide the appropriate prevention strategy. Both focus on improving the individual's risk factor profile, and secondary prevention methods further depend on the stroke mechanism. For ischemic stroke, these mechanisms include atherothrombotic, small-vessel (or "lacunar"), cardioembolic, stroke due an unknown or yet to be determined etiology (or "cryptogenic"), and, finally, "other," a category that captures rare and unusual stroke types. Multiple randomized controlled trials have been conducted over the past half-century evaluating optimal stroke prevention strategies, especially for atherothrombotic and cardioembolic stroke subtypes.

Hemorrhagic strokes account for 15% to 20% of all strokes and are further divided into subarachnoid hemorrhage (SAH) and intracerebral hemorrhage (ICH). Causes of SAH include trauma, berry or congenital aneurysms, and, less often, arteriovenous malformations. The ICH is most commonly caused by hypertension and cerebral amyloid angiopathy (CAA). Appropriate classification of a stroke and its etiology aids the clinician in determining the most effective prevention strategy.

PRIMORDIAL STROKE PREVENTION

The INTERSTROKE case-control study among 22 countries determined that 10 risk factors accounted for nearly 90% of strokes. Listed in order of significance, they are as follows: hypertension, cardiac disease, current smoking, waist-to-hip ratio, poor diet, sedentary lifestyle, excessive alcohol intake, diabetes mellitus, depression, and psychosocial stress. The highest burden of stroke in the United States falls in the so-called "stroke belt" located in the southeast, where high prevalence of diabetes, hypertension, obesity, and a number of social determinants of cardiovascular health cluster together to increase stroke incidence and related mortality. Population level prevention of stroke in such areas relies on improving cardiovascular health through campaigns aimed at increasing stroke awareness, improving diet and physical activity, and limiting exposure to tobacco products.

Diet

The Mediterranean diet may protect against cardiovascular disease, including stroke. It is characterized by high intake of fruits, vegetables, and legumes; olive oil as the principal source of fat; moderate consumption of fish and poultry, with minimal intake of red meat and dairy; and an option of mild to moderate consumption of red wine, mostly with meals. Compared to a low-fat diet, this complex combination of nutrients decreased 5-year stroke risk by approximately 30% in a prospective study. In general, any diet aimed at promoting cardiovascular health,

such as the Mediterranean diet or the Dietary Approach to Stop Hypertension diet, revolves around the central notions of a high intake of plant-based nutrients, low-salt intake, and a curbing of saturated fats and simple sugars.

Smoking

Tobacco use is strongly discouraged, and among smokers, cessation of smoking leads to a reduction in stroke risk to levels similar to nonsmokers by 5 years. It is still unclear how much e-cigarettes, or "vaping," affects stroke risk, but early data suggests an increased risk of stroke in e-cigarette users; risk is even higher in those who use both e-cigarettes and conventional cigarettes compared to never users.

Exercise

Physical activity is associated with a reduced risk of stroke, and importantly, several studies provide evidence that only a moderate level of activity is required, and so physical activity should be encouraged even among the elderly. A sedentary lifestyle, in combination with consumption of simple carbohydrates, has contributed to one-third of Americans becoming obese and to even more becoming overweight. Obesity is an independent risk factor for stroke, even after adjusting for physical activity and diet. Obesity is comorbid with diabetes, hypertension, and heart disease.

PRIMARY STROKE PREVENTION

Like primordial stroke prevention, primary stroke prevention aims to limit the risk of first-time stroke, but instead of addressing large groups of people, the health care provider focuses on each individual separately. Specific targets for intervention are a person's major modifiable risk factors, including hypertension, diabetes mellitus, hypercholesterolemia, and atrial fibrillation (AF). Several randomized trials have demonstrated the benefits of specific interventions to prevent a first stroke among patients with certain stroke risk factors (**Table 45.1**).

Hypertension

Blood pressure is the most important contributor to stroke incidence, increasing the risk of stroke in a linear fashion. High blood pressure accounts for at least 35% of all strokes. β-Blockers, thiazide diuretics, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and calcium channel blockers are the most widely studied agents in stroke prevention. Although calcium channel blockers may provide the greatest neurovascular protection, they are also associated with an increased risk of heart failure. The general consensus is that protection against stroke depends on the level of blood pressure control rather than on the specific class of medication used. Blood pressure reductions of 10 mm Hg systolic or 5 mm Hg diastolic have been shown to reduce risk of first-time stroke by more than 40% LEVEL 1.[1] In the United States, efforts targeting hypertension have contributed to the steady decline in stroke incidence and stroke-related mortality in the last half-century.

The effects of adequate blood pressure management may be more robust in those with diabetes mellitus. The ACEIs and ARBs are recommended because they have been proven renoprotective and also effective in reducing cardiovascular events and specifically stroke in those with diabetes mellitus. Intensive blood pressure management has also proven effective in those over 75 years of age. The Randomized Trial of Intensive versus Standard Blood Pressure Control (SPRINT) trial demonstrated that intensive blood pressure management (defined as systolic blood pressure less than 120 mm Hg) led to a significantly lower incidence of the composite cardiovascular outcome that included stroke, compared to standard blood pressure goals. It is therefore widely accepted that lifelong blood pressure management holds central importance in the primary prevention of stroke.

TABLE 45.1 Evidence-Based Primary Stroke Prevention

Risk Factor	Treatment
Hypertension	Antihypertensive
Myocardial infarction	HMG-CoA reductase inhibitor
Hyperlipidemia	HMG-CoA reductase inhibitor
Atrial fibrillation	Warfarin or oral anticoagulants
DM/vascular disease	ACE inhibitor
Asymptomatic carotid stenosis (60%-99%)	Consider carotid endarterectomy.
"High-risk" populations	HMG-CoA reductase inhibitor

Abbreviations: ACE, angiotensin-converting enzyme; DM, diabetes mellitus; HMG-CoA, hydroxymethylglutaryl-coenzyme A.

Diabetes Mellitus

Epidemiologic studies show a positive relationship between hyperglycemia and stroke incidence, but aggressive management of hyperglycemia may actually be harmful. In the Action to Control Cardiovascular Risk in Diabetes study, investigators compared intensive glucose-lowering therapy with a goal glycated hemoglobin level below 6% to a glycated hemoglobin goal of 7% to 7.9%. They found no difference in stroke incidence, with a slight, but statistically significant, increase in overall mortality in the group undergoing tight control. Similarly, postprandial hyperglycemia and glycemic variability have both been associated with increased cardiovascular disease burden in epidemiologic studies, but prospective studies have not shown any benefit. Current recommendations are for a glycated hemoglobin goal of less than 7% LEVEL 1.[2]

The presence of diabetes also has ramifications for the management of other risk factors, specifically low-density lipoprotein (LDL) cholesterol. Diabetes is considered a cardiovascular disease equivalent, and those 40 to 75 years of age with diabetes should be placed on a hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor or statin, unless there is a contraindication LEVEL 1.[3]

Hypercholesterolemia

Large studies, such as the Multiple Risk Factor Intervention Trial that included over 350,000 men, have shown a positive association between death from ischemic stroke and increased cholesterol levels. There has also been evidence of a relationship between hemorrhagic strokes and low cholesterol levels. In line with the Multiple Risk Factor Intervention Trial data, trials using HMG-CoA reductase inhibitors among cardiac and other high vascular disease risk patients have demonstrated benefits in terms of stroke risk reduction, in addition to the effects on cardiac event rates. The effect on stroke risk is more modest, however, probably reflecting the fact that stroke is more heterogeneous than heart

disease and less strongly linked to elevated cholesterol levels.

In the Heart Protection Study, a randomized, multicenter, placebo-controlled trial of simvastatin therapy, there was a 25% risk reduction for stroke (from 5.7% to 4.3%; $P < .0001$), without an increase in risk of hemorrhagic stroke over a 5-year period. Importantly, these benefits remained in those with LDL less than 100 mg/dL.

Evidence suggests that the optimal way to think about cholesterol goals within the context of primary stroke prevention is to consider the individual's long-term absolute risk of combined cardiovascular events. The Pooled Cohort Risk Assessment Equations was developed by the American College of Cardiology and American Heart Association using data from several large epidemiologic studies to predict a 10-year risk of cardiovascular events and identify appropriate candidates for statin therapy. Those with a high risk of cardiovascular events (considered to be at least 7.5% over 10 y) should be placed on cholesterol-lowering therapy, independent of specific risk factors. Other high-risk groups that should receive statin therapy are individuals with an LDL greater than 190 mg/dL and those aged 40 to 75 years with comorbid diabetes mellitus LEVEL 1.[3]

Proprotein convertase subtilisin-kexin type 9 (PCSK9) inhibitors are a novel class of drugs whose therapeutic class effect is through promoting the degradation of LDL receptors, thereby decreasing LDL levels far beyond that of statins alone. The Evolocumab and Clinical Outcomes in Patients with Cardiovascular Disease (FOURIER) trial enrolled nearly 30,000 participants with an elevated LDL who were already on a statin and found a modest but statistically significant absolute risk reduction of ischemic stroke (0.4%), over a 2-year period. Hemorrhagic stroke was not affected. Alirocumab was also shown to have a similar effect on stroke risk in a more recent trial of high–cardiovascular risk patients with elevated LDL levels despite statin therapy. A major limitation to using PCSK9 inhibitors is cost. The PCSK9 inhibitors can therefore be considered in very high–cardiovascular risk patients with elevated LDL levels despite otherwise maximal lifestyle and medical management LEVEL 1.[3]

Atrial Fibrillation

Cardioembolic stroke accounts for approximately 15% to 30% of all ischemic strokes. Compared to stroke related to small-vessel disease and large-vessel atherosclerosis, it is associated with a longer hospital stay, greater levels of residual disability, and higher rates of stroke-related mortality. The AF is the most common cause of cardioembolic stroke. Anticoagulation is effective in preventing both incident and recurrent strokes in patients with AF LEVEL 1.[4] Warfarin, a vitamin K antagonist associated with a 60% to 70% relative risk reduction in stroke, was formerly the only available oral anticoagulant for long-term use, but several anticoagulants that directly inhibit factor Xa and thrombin are now available, with more still in the development phase. Large randomized clinical trials have compared warfarin to these direct-acting oral anticoagulants (DOACs, including dabigatran, apixaban, rivaroxaban, and edoxaban) and have shown similar or slightly better efficacy with the newer agents. Some of the trials also indicate a lowered risk of intracranial hemorrhage with little need for serum monitoring. Additionally, left atrial appendage closure devices are an alternative to long-term drug therapy, particularly among patients at increased risk for hemorrhagic complications. In the Stroke Prevention in Atrial Fibrillation study, anticoagulation reduced stroke recurrence substantially, even in patients older than 75 years.

Risk of stroke is associated with the following risk factors: age older than 65 years, female sex, previous embolization, sustained hypertension, congestive heart failure, peripheral vascular disease, and diabetes mellitus. With a history of embolization alone or a combination of any other two risk factors, the stroke incidence is nearly 3% per year and increases to 18% when all risk factors are present. In patients with nonvalvular AF, and a low hemorrhagic risk, anticoagulation is typically recommended if the personalized annual stroke risk is approximately 3% or greater LEVEL 1.[4]

Carotid Stenosis

Another major source of preventable cerebral infarction is large-vessel atherosclerotic disease and, specifically, internal carotid artery stenosis. In asymptomatic patients with greater than 60% carotid stenosis and low perioperative risk, carotid endarterectomy (CEA) should be considered with the expectation that approximately 20 procedures must be performed to prevent one stroke over a 5-year period. Men are more likely to benefit than women, which along with the patient-specific perioperative risk, helps the clinician decide whether or not to recommend surgery. However, modern-day medical therapy with potent lipid-lowering medications and novel blood pressure agents has changed since the original carotid revascularization trials were performed. The Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Study, an ongoing multicenter clinical trial, hopes to provide definitive evidence regarding the best treatment in patients with asymptomatic high-grade stenosis. Although CEA is the gold standard, carotid artery stenting (CAS) is another viable alternative; it is also being studied in the Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Study and may be employed if the anatomy is unfavorable to surgical intervention. There is no benefit of either procedure in patients with less than 50% stenosis or in chronic carotid occlusion.

SECONDARY STROKE PREVENTION

Once a stroke or TIA has occurred, the goals of the clinician are to minimize long-term disability and direct management to prevent another stroke. Secondary stroke prevention measures do not alter progression of the initial stroke, but research has shown that initiating preventive therapy in the acute setting after stroke has an immediate impact on the recurrence risk and further increases the likelihood of preventive therapy being in place in the long term (**Fig. 45.1**).

Stroke Mechanism and Evaluation

Therapies aimed at limiting risk of recurrence depend in large part on the mechanism of the stroke, its severity, and the individualized modifiable risk factor profile. Because the risk of a repeat stroke is highest in the first 2 weeks after the initial event, a comprehensive evaluation must be employed as soon as possible to determine stroke mechanism and quantify the underlying risk factors. The importance of a good history and physical examination cannot be overstated and should be followed by hypothesis-driven diagnostic testing.

Neuroimaging

Magnetic resonance imaging of the brain visualizes acute ischemic injury and can aid in determining the mechanism. Although lacunar strokes, or deep punctate infarcts within the white matter

FIGURE 45.1 Effect of secondary stroke prevention measures on stroke recurrence. Estimated absolute risk reductions in stroke of various secondary stroke prevention therapies compared to placebo or in some cases, standard management. [a]Refers to symptomatic carotid stenosis of 70% to 99%. [b]Warfarin or direct oral anticoagulants. [c]Compared to single antiplatelet agent and not including dual antiplatelet therapy initiated in the acute setting after stroke.

predominantly occur from small-vessel disease, for example, large superficial wedge-shaped infarcts or multifocal infarcts are more consistent with embolism. Extracranial vessel imaging is a crucial step in the diagnostic algorithm, whereas intracranial vessel imaging in the form of magnetic resonance angiography or computed tomography angiography may be useful to identify intracranial stenosis. The gold standard for carotid imaging is digital subtraction angiography, but it is impractical for screening purposes. Carotid Doppler has therefore become the main screening test for carotid atherosclerosis, whereas the widespread availability of magnetic resonance angiography and computed tomography angiography provides alternatives to be used at the clinician's discretion and, if needed, to confirm the findings on ultrasound.

Cardiac Evaluations

Transthoracic echocardiography is used to assess structural cardiac abnormalities that predispose to cardioembolism. In cases with a high pretest probability of embolism, transesophageal echocardiography can be used to better visualize the left atrium and cardiac valves, looking for intra-atrial thrombus, cardiac myxoma, or valvular vegetations. A second arm of the cardiac evaluation assesses the cardiac rhythm for evidence of AF. Electrocardiography and cardiac telemetry are used in screening, whereas prolonged monitoring for several weeks to months, and even years in some cases, can be very helpful in capturing occult AF.

Blood Work and Other Laboratory Testing

Measuring LDL, high-density lipoprotein, hemoglobin A_{1c}, and—in appropriate or otherwise unexplained cases—erythrocyte sedimentation rate; C-reactive protein; rapid plasma reagin; or hypercoagulability testing allows for proper management and prevention of recurrent stroke. Rarely, given the right clinical context, a patient may require evaluation for underlying genetic, infectious, or inflammatory disorders. Examples include cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, Fabry disease, varicella zoster virus cerebral vasculopathy, human immunodeficiency virus vasculopathy, syphilitic arteritis, and cerebral involvement of any one of the systemic inflammatory vasculitides. Evaluation for these

FIGURE 45.2 Common vascular mechanisms of ischemic stroke. Abbreviations: ICAD, intracranial atherosclerotic disease; LA, left atrial; LV, left ventricle; PFO, patent foramen ovale.

more uncommon disorders is typically achieved through a combination of specialized serum or genetic tests, advanced imaging, and cerebrospinal fluid analysis (Fig. 45.2).

Prevention Early After Transient Ischemic Attack and Stroke

It is important to recognize that TIAs call for the same urgency in evaluation as proven strokes. Johnston et al showed that the risk of stroke after TIA is about 5% in the first 2 days and 10% within 90 days. Further, 1 in 20 individuals will suffer a fatal or disabling stroke within 90 days after TIA. Trials have shown that urgent evaluation and directed management of TIA or minor stroke dramatically decreases the recurrence rate of stroke.

Early interventions aimed at stroke prevention revolve around mitigating high-risk situations, such as moderate- to high-grade carotid stenosis and AF. Dual antiplatelet therapy in the realm of stroke prevention has been reserved for preventing recurrent events in patients presenting with high-risk TIA or minor stroke. The Clopidogrel in High-Risk Patients With Acute Non-disabling Cerebrovascular Events (CHANCE) trial found that a 21-day course of dual antiplatelet therapy with aspirin and clopidogrel among Chinese patients with TIA and minor stroke, given within 24 hours of symptom onset, lowered the 3-month stroke recurrence rate. The more recent Clopidogrel and Aspirin in Acute Ischemic Stroke and High-Risk TIA (POINT) trial confirmed the findings from CHANCE, making a short course of aspirin and clopidogrel in the early period after stroke a recommended treatment for patients with high-risk TIA or minor stroke. Initiating therapy outside of the 24-hour window, maintaining treatment for longer than 3 months, or treating patients with moderate to severe stroke limits benefit and increases the risk of harm, mostly in the form of major hemorrhage. Short-term heparin is not effective in preventing stroke recurrence compared to aspirin, according to the International Stroke Trial, which enrolled nearly 20,000 ischemic stroke patients; similar findings were seen in the Chinese Acute Stroke Trial with nearly the same number of patients.

Antiplatelet Therapy

All patients with ischemic stroke without a definite indication for anticoagulation or dual antiplatelet therapy, and in whom no contraindication is present, should receive long-term single antiplatelet therapy. Aspirin monotherapy, the combination of aspirin with extended-release dipyridamole or clopidogrel are all acceptable options for initial therapy in the secondary prevention of noncardioembolic stroke LEVEL 2.[5]

Mechanism of Action and Dosing

The action of aspirin is to irreversibly acetylate and inhibit platelet cyclooxygenase-1, which stops synthesis of the powerful platelet aggregant thromboxane A2. Lower doses of aspirin have the advantage of minimizing inhibition of endothelial cell production of prostacyclin (PGI2), the powerful platelet antiaggregant. The concept of a balance between thromboxane A2 and PGI2 in the normal circulation without aggregate formation won Sir John Vane a Nobel Prize. Dipyridamole acts in conjunction with aspirin by increasing adenosine and PGI2, two potent antiaggregants. The optimum daily dose of aspirin remains somewhat controversial, but doses as low as 30 mg daily appear effective and have less side effects, such as gastrointestinal bleeding. The U.S. Food and Drug Administration currently recommends doses between 50 and 325 mg daily for stroke prevention.

Clopidogrel, a thienopyridine derivative, blocks platelet activation and aggregation by irreversibly inhibiting the P2Y12 ADP receptor. It is increasingly being used for secondary stroke prevention. Cilostazol is a phosphodiesterase 3 inhibitor used in peripheral arterial disease that has proven to reduce recurrence of stroke in Asian populations but is less well studied and therefore not widely used in stroke prevention in the United States. In general, the risk of adverse events with standard antiplatelet agents is very low, but a few points need to be considered: (1) Treating with the combination of aspirin and dipyridamole

requires twice-daily dosing and is complicated by a high rate of secondary headache and gastrointestinal symptoms, thus reducing patient compliance; (2) higher doses of aspirin increase bleeding risk without providing clinical benefit; (3) clopidogrel can cause diarrhea, thrombocytopenia, rash, and, in very rare circumstances, thrombotic thrombocytopenic purpura; and (4) patient variability in the cytochrome P450 2C19 gene may impair metabolism to the active clopidogrel metabolite, effectively decreasing response to clopidogrel.

Impact on Outcomes

As a group, antiplatelets offer an absolute risk reduction of 2% in annual vascular events (myocardial infarction, stroke, and death), with a 0.1% to 0.2% increase in major extracranial hemorrhages (number needed to harm is 500-1,000 to cause one major extracranial hemorrhage). There may also be a modest benefit of clopidogrel, or aspirin with dipyridamole, over aspirin alone for prevention of recurrent strokes, according to some meta-analyses. Aspirin with dipyridamole compared to aspirin alone produced an approximate annual absolute risk reduction of 1% in two large clinical trials. On the other hand, clopidogrel and the combination of aspirin with dipyridamole produced nearly identical results in one study. Choice of antiplatelet depends on the setting, comorbidities, and access to health care, but aspirin is the most widely studied and least expensive medication, making it ideal for large-scale use especially in developing countries where the number treated is usually determined by the cost of therapy. Clopidogrel and aspirin with dipyridamole are reasonable alternatives as first-line therapy or second-line therapy in those who have suffered a stroke while on aspirin.

Dual Antiplatelet Therapy

More recently, dual antiplatelet therapy with clopidogrel and aspirin, compared to aspirin alone, has been investigated in secondary prevention after lacunar stroke in the Secondary Prevention of Small Subcortical Strokes (SPS3) trial. There was no evidence of a reduction in risk of stroke recurrence, despite an increase in risk of bleeding and mortality, among those treated with dual antiplatelet therapy. There are several reasons that may account for the difference in results between the CHANCE and POINT trials described earlier and SPS3: (1) CHANCE and POINT provided antiplatelet therapy within 24 hours of stroke onset; (2) CHANCE and POINT also included patients with mild stroke and TIA, isolating a group with low risk of hemorrhagic conversion; and (3) they studied the use of dual antiplatelet agents for a short period of time followed by a single antiplatelet agent, whereas SPS3 enrolled patients within 6 months of stroke onset and used dual antiplatelet therapy for the duration of the trial. The majority of the benefit from dual antiplatelet therapy occurs within the first week of treatment, whereas treatment with dual antiplatelets beyond 3 months of stroke onset increases risk without added benefit. This immediate reduction in recurrent vascular events is a phenomenon echoed in trials that studied dual antiplatelet agents within 24 hours of cardiac ischemia.

Anticoagulation

Anticoagulation with warfarin is indicated in patients with definite cardioembolic sources of stroke, such as mechanical valves or left ventricular thrombus. In patients with nonvalvular AF, anticoagulation with warfarin or a DOAC (described earlier) is indicated.

Carotid Endarterectomy, Angioplasty, and Stenting

In good surgical candidates, the treatment of choice for stroke and TIA caused by carotid stenosis of equal to, or greater than, 70% of the vessel diameter is CEA by a skilled surgeon with an acceptable complication rate (<5%) combined with optimal medical management, as demonstrated by three prospective studies: the North American Symptomatic Carotid Endarterectomy Trial, the European Carotid Surgery Trial, and the U.S. Veterans Affairs Cooperative Study on CEA LEVEL 3.[5] The first published case of successful CEA was performed by DeBakey in 1954, but it was not until 1991 that these studies confirmed its benefits. In those with high-grade carotid stenosis, CEA yields a number needed to treat of 16 to prevent one stroke over a 1-year period. There is also a benefit, albeit more modest, of CEA in symptomatic patients with moderate carotid stenosis (50%-69%). Post hoc analysis has also demonstrated that the greatest value of CEA is within 2 weeks of the event, and contemporary literature argues for intervention as soon as is medically possible.

More recently, CAS has been compared to CEA in three large trials: Stent-Protected Angioplasty Versus Carotid Endarterectomy, the International Carotid Stenting Study, and the Carotid Revascularization Endarterectomy versus Stenting Trial. Results have been consistent in showing a slight increase in periprocedural stroke (30 d) with CAS compared to CEA. In Stent-Protected Angioplasty Versus Carotid Endarterectomy and Carotid Revascularization Endarterectomy versus Stenting Trial, combined adverse outcomes over a 2-year period were similar, whereas International Carotid Stenting Study showed that CEA was superior in combined outcomes both in the acute and long-term settings. Although CEA remains the treatment of choice for symptomatic high-grade carotid stenosis, CAS is an alternative that can be employed in high-risk surgical patients or those with unsuitable anatomy. Transcarotid arterial revascularization is a stenting approach that uses direct carotid puncture and blood flow reversal, thereby providing distal embolization protection. It is increasingly being used in a subset of patients with lesions that are otherwise difficult to access.

There have been a number of trials looking at strategies for preventing stroke from intracranial stenotic lesions that are not readily accessible to surgeons. Stroke distal to a 50% to 99% vascular stenosis carries an estimated recurrence rate of 15% in the first year. In the Warfarin and Aspirin for Symptomatic Intracranial Stenosis trial, investigators studied aspirin versus warfarin in patients with symptomatic intracranial stenosis 50% to 99%. The study was stopped because of a high rate of adverse events in the warfarin group, leading researchers to conclude that warfarin provides no benefit over aspirin in patients with intracranial stenosis. Despite the negative primary result, the study provided the important finding that risk was highest in patients with greater than 70% stenosis, a group that had a 25% stroke recurrence rate in the first year. The subsequent Stenting versus Aggressive Medical Therapy of Intracranial Atherosclerotic Stenosis trial thus targeted patients with recent stroke and high-grade intracranial stenosis (>70%), comparing percutaneous transluminal angioplasty and stenting with best medical management with aggressive risk factor control. Both groups received dual antiplatelet therapy with aspirin and clopidogrel for 3 months. There was also aggressive management of risk factors including hypertension, lipids, diabetes, and tobacco use. The primary end point of recurrent stroke or death was reached in 20% of the stenting group as opposed to 12% in the medical

management group. Interestingly, the medical group had a lower than expected stroke recurrence rate compared to the 25% risk predicted by the Warfarin and Aspirin for Symptomatic Intracranial Stenosis study. The results suggested that aggressive medical therapy is superior to intervention for high-grade intracranial stenosis with currently available technology.

Cardiac Abnormalities

Treatment of cardiogenic emboli depends on the offending pathology. Infected prosthetic valves need replacement, and emboli from a benign tumor called myxoma require surgical removal of the tumor (**Table 45.2**). The role of anticoagulation among patients with possible paradoxical embolism through a patent foramen ovale (PFO) depends on the presence of an identified venous thrombus. In those without another identified stroke etiology or venous thrombosis, the closure of a PFO using transcardiac devices can reduce secondary stroke based on results of several large prospective trials comparing closure to medical therapy. Although initial trials did not show benefit of PFO closure when compared to medical therapy alone, follow-up trials that limited enrollment criteria to relatively young patients (younger than 60 y) with recent cryptogenic stroke and absence of extracranial or intracranial atherosclerotic disease found a modest benefit in stroke prevention with PFO closure compared to antiplatelets alone. A meta-analysis by Ntaios et al published in 2018 combined the results of five trials (n = 3,627 patients). It showed that PFO closure using a percutaneous transcatheter approach led to a 2.1% absolute risk reduction of stroke over the course of 3.7 years (number of patients needed to treat to prevent one stroke per year approximately 170). Patient preference, future need for anticoagulation, and procedural complications including AF must all be considered before recommending PFO closure.

To aid in decision making regarding PFO closure, clinicians may apply the Risk of Paradoxical Embolism scoring system, in which the attributable risk of stroke from a PFO increases when a patient is young; has a cryptogenic embolic-appearing infarct; and lacks the common stroke risk factors of hypertension, diabetes mellitus, cigarette smoking, and previous stroke (**Table 45.3**).

TABLE 45.2 Cardioembolic Sources of Stroke

High Risk	Low Risk/Unknown Risk
Atrial fibrillation	Cardiomyopathy
Mechanical prosthetic valve	Aortic arch atheroma
Recent myocardial infarction	Patent foramen ovale
Left ventricular thrombus	Atrial septal aneurysm
Rheumatic heart disease	Mitral valve strands
Marantic endocarditis	
Atrial myxoma	
Infective endocarditis	

TABLE 45.3 Risk of Paradoxical Embolism (RoPE) Score Used to Predict Attributable Risk of Stroke From Patent Foramen Ovale[a]

RoPE Score			Example Stroke Patients, Both of Whom Have Patent Foramen Ovale Identified on Their Echocardiography	
Age at time of index event:	Points		20-y-old healthy video gamer with no past history other than smoking and acute onset of aphasia and small left frontal opercular infarction	75-y-old woman with a history of diabetes and hypertension and acute onset left hemiparesis, with acute right internal capsule infarction and multifocal chronic small-vessel disease
18-29 y	5			
30-39 y	4			
40-49 y	3			
50-59 y	2			
60-69 y	1			
>70 y	0			
Age points			5	0
	No	Yes		
No history of hypertension	0	1	1	0
No history of diabetes	0	1	1	0
No history of stroke or TIA	0	1	1	1
No history of smoking	0	1	0	1
Peripheral (superficial, cortical) infarct on CT or MRI	0	1	1	0
Total RoPE score			9	2
Approximate likelihood stroke attributable to patent foramen ovale (attributable fraction)			88%	0%
Approximate risk of stroke recurrence over 2 y			20%	2%

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging; TIA, transient ischemic attack.

[a]Adapted from Kent DM, Ruthazer R, Weimar C, et al. An index to identify stroke-related vs incidental patent foramen ovale in cryptogenic stroke. *Neurology*. 2013;81(7):619-625.

Aortic arch atheromatous plaque is another condition associated with increased risk of stroke, with retrospective case-control studies consistently showing an association. Complex plaques, defined by a protruding component greater than 4 mm, presence of a mobile component, or intraplaque ulceration, are deemed high risk for embolization. Despite the known association, a causal relationship between aortic arch atheroma and stroke has never been proven, mirroring the uncertainty in therapeutic recommendations. There is no clear evidence to support use of anticoagulation, even in complex plaques. Statins are recommended because of their potential to remodel and cause regression in atheromatous plaques, along with standard antiplatelet therapy for secondary stroke prevention.

MODIFIABLE RISK FACTOR MANAGEMENT

Hypertension

Recent studies have provided evidence for increased use of antihypertensive agents in patients with stroke and TIA. Despite evidence of the efficacy of blood pressure reduction in reducing risk of a first stroke, concerns about lowering blood pressure in patients with existing cerebrovascular disease remained due to the theoretical possibility that in patients with arterial disease of cerebral vessels, a reduction in blood pressure could worsen perfusion and precipitate clinical events or affect cognition.

Much has been made of the potential benefits of ACEIs or ARBs in stroke prevention. This has been an attractive hypothesis, but the data does not provide an entirely convincing picture regarding the privileged position of ACEIs and ARBs among antihypertensive agents, particularly after stroke. Although patients with diabetes should probably receive these medications for prevention of progression of renal disease, it is not clear that this therapy dramatically reduces the incidence of stroke beyond what would be expected from reducing the blood pressure to a similar degree using other agents. The Perindopril Protection Against Recurrent Stroke Study (PROGRESS) trial was designed and conducted in large part to address these concerns. The PROGRESS was a randomized, double-blind, placebo-controlled trial of antihypertensive therapy among 6,105 patients with a history of hemorrhagic or ischemic stroke or TIA. Patients were enrolled independent of hypertension status, and 52% were nonhypertensive—considered to be systolic blood pressure 160 mm Hg or lower and diastolic blood pressure 90 mm Hg or lower—the blood pressure thresholds in use at the time the study started. Active treatment used the ACEI perindopril, with or without the thiazide diuretic indapamide. Active therapy led to a mean blood pressure reduction of 9/4 mm Hg compared with placebo, with a statistically significant 28% relative risk reduction in recurrent stroke or an absolute risk reduction of 4%. Of particular interest, the benefit of combination therapy was of a similar magnitude among hypertensive and nonhypertensive patients. There was also greater benefit for those with initial hemorrhagic stroke (relative risk reduction 49%) than for those with ischemic stroke (relative risk reduction 26%), likely reflecting the even stronger association of blood pressure with hemorrhagic stroke risk. The PROGRESS has therefore been interpreted as indicating a benefit for blood pressure reduction among patients with cerebrovascular disease, independent of a history of hypertension.

The SPS3 study, aside from studying the effect of dual antiplatelet therapy, also examined the role of strict versus standard blood pressure management (systolic <130 vs 130-149 mm Hg) on the outcome of stroke recurrence among patients with small-vessel (lacunar) strokes. It showed a trend toward benefit in stroke recurrence in the lower blood pressure group (hazard ratio 0.81, 95% confidence interval 0.64-1.03). Current guidelines recommend blood pressure lowering based on individualized targets, but it is reasonable to use a systolic blood pressure goal of less than 140 mm Hg and diastolic less than 90 mm Hg LEVEL 1.[6] Reducing daily salt intake to 2 g, engaging in regular physical activity, and losing weight in overweight or obese patients may also have substantial benefits on blood pressure levels, apart from use of pharmacologic therapy.

Hyperlipidemia

Hyperlipidemia is another important modifiable risk factor for vascular disease, although its relationship to stroke is less clear than that for heart disease. The Stroke Prevention by Aggressive Reduction of Cholesterol Levels trial provides direct evidence of the benefit of statin therapy in secondary prevention of stroke among patients presenting with stroke or TIA. The Stroke Prevention by Aggressive Reduction of Cholesterol Levels trial enrolled 4,731 patients with stroke or TIA within the previous 6 months, and at least 30 days, after stroke. Patients were required to have baseline LDL cholesterol levels between 100 and 190 mg/dL. Those with AF, cardioembolism, and SAH were excluded, and patients were randomized to atorvastatin 80 mg daily or to placebo. Over a median duration of follow-up of nearly 5 years, atorvastatin reduced the risk of recurrent stroke from 13.1% to 11.2%. Effects on other cardiovascular outcomes were slightly greater, but there was no effect on overall mortality.

Because lipids are not thought to contribute greatly to stroke risk, some of this benefit may derive from the anti-inflammatory or other effects of statins. Other putative mechanisms through which statins may exert their effects include effects on blood flow and vascular endothelial function, inflammation, free radical scavenging, hemostasis, and others.

Statins are the mainstay in lipid reduction therapy, and aggressive lipid-lowering treatment should be employed after a stroke or TIA LEVEL 1.[3] As discussed in the section on primary stroke prevention, PCSK9 inhibitors should be considered in patients with a history of stroke whose LDL levels remain elevated despite aggressive statin therapy and efforts to maximize lifestyle related factors.

Diabetes Mellitus

Although glycemic control has been shown to reduce risks of microvascular complications, the benefit in reducing macrovascular complications, such as stroke, is less certain. In one trial, tight glycemic control of a prospective cohort of newly diagnosed diabetics was not found to significantly reduce stroke risk. Nonetheless, among sufferers of stroke who have concomitant diabetes, diet and exercise, oral hypoglycemic drugs, and insulin are recommended to obtain appropriate glycemic control.

Lifestyle Modification

Behavioral risk factors may be most difficult to control, but physicians should endeavor to educate patients about their importance. Smoking is addictive, and cessation may necessitate

psychological counseling and medical aids, such as nicotine patches or varenicline. Physical activity should be encouraged, as a sedentary lifestyle is associated with elevations in blood pressure and stroke risk. Alcohol consumption in excess of two drinks daily should be discouraged, although there is evidence that moderate alcohol consumption may have protective effects against stroke risk. However, proof that control of these risk factors reduces stroke risk is difficult to obtain from randomized trials. Patient education regarding behavioral risk factor control is extremely important and is similar for both primary and secondary stroke prevention LEVEL 7.[4,5]

HEMORRHAGIC STROKE

Intracerebral Hemorrhage

The ICH accounts for approximately 10% to 15% of all strokes in the United States and carries a 1-year mortality close to 60%. Other than hypertension, spontaneous ICH can be caused by CAA or angiitis, anticoagulation therapy, vascular malformations, brain tumors, cavernous angiomas, aneurysms, cerebral vein thrombosis, illicit drugs or alcohol abuse, pathologic coagulopathy, infectious or inflammatory arteritis, and genetic vasculopathies. Massive ICH of more than 60 mL in volume is often lethal if surgical evacuation is not performed because vital structures are irreversibly damaged, whereas smaller hemorrhages may be treated with supportive care. Given the dismal 1-year prognosis even with small- to moderate-sized hemorrhage, primary prevention of ICH is of the upmost importance.

Hypertension

As with ischemic stroke, first-time ICH can in many cases be avoided through identification and management of specific risk factors. Hypertension is the most important modifiable risk factor and doubles the risk of first-time spontaneous ICH. Blood pressure control lowers the risk of ICH recurrence by nearly 50%. Annual recurrence is 2% of those with a deep location and as high as 4% of those with a lobar localization. The higher risk of recurrence with lobar hemorrhage likely represents the occurrence of CAA.

Cerebral Amyloid Angiopathy

The CAA is not yet modifiable. The CAA-associated microhemorrhages and microinfarcts are much more common than clinically evident bleeds. The biggest risk factors for recurrent CAA-associated hemorrhages are age, the number of microbleeds present at baseline, and the presence of the apolipoprotein E E2 or E4 alleles. Amyloid-depleting therapy is currently not approved for clinical use, limiting attempts at secondary prevention.

The PROGRESS trial, discussed earlier, studied a subset of patients with recurrent ICH and determined that blood pressure lowering by systolic/diastolic of 9/4 mm Hg decreased risk of cumulative ICH by 50%, and by over 70% in those with presumed CAA, establishing the viability of a traditional risk prevention approach in those with CAA-related hemorrhage. Many studies reported an association of HMG-CoA reductase inhibitors with an increased risk of ICH, but that concern was ultimately refuted by a large meta-analysis that included over 40 trials with nearly 250,000 individuals. Nonetheless, there is no benefit for statins in the prevention of ICH, although they may be used in those with previous ICH who have other indications, such as cardiovascular disease or ischemic stroke.

Issues Related to Risk of Hemorrhage

Anticoagulation-Associated Hemorrhage

The rates of major hemorrhage were compared among the DOACs and warfarin in a meta-analysis among 102,607 patients. The risk of major hemorrhage was about 28% lower among those on DOACs, and the risk of ICH was about 50% lower; there was no difference in risk of gastrointestinal bleeding. The incidence of ICH was 0.51% in the DOAC group and 1.08% in the warfarin group. Despite the relatively small absolute risk of ICH, chronic oral anticoagulation may be contraindicated if there are patient-specific factors, such as previous major hemorrhage, that may significantly increase the risk of future hemorrhage.

Management of Atrial Fibrillation in Patients at High Risk for Intracerebral Hemorrhage

Patients with a history of symptomatic hemorrhage thought to be related to CAA carry a relative contraindication for chronic anticoagulation. An alternative for such patients is left atrial appendage closure. Closing the atrial appendage was first theorized as a way to prevent AF-related thromboembolism, as an estimated 90% of thromboembolic material originates in the atrial appendage in patients with nonrheumatic AF. The two ways to achieve atrial appendage closure and make it functionally obsolete are through surgical ligation or through a catheter approach using the WATCHMAN device. The catheter-based approach involves venous catheterization and atrial septal puncture before insertion and deployment of the closure device in the atrial appendage. Randomized controlled trials comparing these devices to warfarin found them to be noninferior in efficacy. Pericardial effusion, periprocedural stroke, and device embolization accounted for the major early complications, whereas device thrombosis and resultant stroke can develop months after implantation. Left atrial appendage closure can therefore be considered in patients who have had a major bleed or carry an increased risk of ICH (**Fig. 45.3**).

Hemorrhage Related to Anticoagulation

Due to ease in administration and limited need for regular monitoring, physicians routinely recommend DOACs over warfarin for the prevention of thromboembolism in patients with nonvalvular AF. In the event of major hemorrhage, such as intracerebral bleeding, warfarin is effectively reversed by fresh frozen plasma or multifactor prothrombin complex concentrate. The development of antidotes for DOACS is an area of intense research. Idarucizumab is a monoclonal antibody against dabigatran and is currently U.S. Food and Drug Administration approved for reversal of dabigatran-related major hemorrhage. For factor Xa inhibitors, andexanet alfa—a modified recombinant inactive form of human factor Xa—has been shown to rapidly and effectively reduce levels of anticoagulant activity and thus decrease hemorrhage burden.

Arteriovenous Malformations

Bleeding from arteriovenous malformations (AVMs) is the most common cause of ICH in those younger than 45 years of age. The Medical Management with or without Interventional Therapy for Unruptured Brain Arteriovenous Malformations (ARUBA) trial

*This algorithm only takes into account patients with primary intracerebral hemorrage. Patients with secondary causes, such as from vascular malformation, should be considered separately.

FIGURE 45.3 Determining the need for atrial appendage closure. For patients with atrial fibrillation, atrial appendage closure should be considered when the risk of future intracerebral or major systemic hemorrhage is deemed insufficiently high, establishing a relative contraindication to anticoagulation. Individuals at very high risk for recurrent intracerebral hemorrhage (ICH) may not be candidates for atrial appendage closure, given the requirement among some practitioners for a concomitant short course of anticoagulation after the procedure. Abbreviation: MRI, magnetic resonance imaging.

evaluated interventional therapy versus medical therapy alone as management of previously unruptured AVMs. The study was stopped early because those in the medical therapy group had a lower risk of stroke or death compared to the intervention group. It is therefore prudent to manage unruptured AVMs conservatively. Heterogeneity of the lesions makes generalization to all AVMs difficult, however, and individual clinician and surgeon experience may also be considered. The AVMs that have ruptured are more likely to rebleed, and surgery, embolization, or stereotactic radiotherapy may be considered when anatomically feasible.

Aneurysmal Subarachnoid Hemorrhage

Extirpation of an aneurysm is the definitive therapy for aneurysms causing SAH and may be accomplished surgically or with balloons, coils, or embolic material deposited in the aneurysm. Prevention of aneurysmal rupture among patients with asymptomatic lesions, however, depends on the natural history of the aneurysm and risk of intervention. The International Study of Unruptured Intracranial Aneurysms defined annual risk of aneurysmal rupture by site and size of the aneurysm in question. The PHASES score was established in 2014 using a pooled analysis of six prospective trials, including over 8,000 individuals, to further help predict risk of aneurysmal rupture. It recognizes seven factors (hypertension, age, history of SAH, anatomic location, size, and geographical location of residence) as predictors of aneurysmal rupture that, when combined into a single score, could more accurately quantify future risk of rupture and help determine the need for intervention. The risk of rupture must be weighed against the risks of the intervention, which are determined by the patient's comorbidities and the historical periprocedural risk of the institution.

STROKE REHABILITATION

A team approach for stroke rehabilitation, starting from a stroke recovery unit with experienced physiatrists and physical, occupational and speech therapists, has proven beneficial for the optimum recovery of patients. This approach is particularly helpful in averting various complications from strokes, such as infections, contractures, and decubitus ulcers, and in maximizing independence for patients with hemiplegia/paresis by teaching them to transfer effectively from bed to wheelchair. Activities of daily living may be optimized for personal hygiene, dressing, and feeding as well. Speech and occupational therapists further help patients improve their skills needed in communication and performance of activities of daily living.

Depression is a frequent accompaniment of stroke, partially as a reaction to physical disability but also because there is altered brain chemistry, which may respond well to selective serotonin reuptake inhibitors and tricyclic antidepressants. One randomized trial found that escitalopram administered prophylactically to stroke patients was effective in preventing the development of depression. A Cochrane review of selective serotonin reuptake inhibitors in the poststroke setting showed them efficacious in improving not only depression but also stroke-related dependence as well as disability. Further studies will be needed to determine whether there is a benefit to prophylactic treatment of depression compared to treatment initiated at the time of diagnosis.

Concussion and Chronic Traumatic Encephalopathy 46

James M. Noble and John F. Crary

KEY POINTS

1. Concussion is a mild traumatic brain injury defined by transient neurologic signs and symptoms, with or without loss of consciousness.
2. Concussion is highly visible in youth and young adult contact and collision sports but occurs more often in nonsports contexts and across the age span.
3. Concussion is further distinguished from other forms of traumatic brain injury by having no evidence of brain injury on standard neuroimaging.
4. Ongoing efforts are working toward a biomarker-based diagnostic and prognostic assessments, but at present, concussion remains a clinical diagnosis.
5. Chronic traumatic encephalopathy is a pathologic entity of uncertain frequency, which occurs almost exclusively in persons with multiple recognized traumatic brain injuries or a history of longitudinal exposure to activities at risk for frequent head contact and injury.
6. The diagnostic hallmark of chronic traumatic encephalopathy is accumulation of abnormal hyperphosphorylated tau in a distinct neuroanatomic distribution, which differentiates it from other neurodegenerative diseases and aging.
7. Traumatic encephalopathy syndrome is a proposed clinical correlate for chronic traumatic encephalopathy, recognizing features including cognitive and behavioral changes, parkinsonism, and motor neuron disease.

CONCUSSION

Introduction

Concussion is a mild traumatic brain injury (TBI) that has been recognized for centuries as an entity in accidents, battle, and sport. The visibility of higher profile cases of recurrent concussion in contact sports and growing concern for potential long-term impacts of concussion have brought it to the fore in recent years. These concerns have particularly focused on potentially vulnerable youths and developing brains. Significant inroads have been made over the past 15 years into understanding the pathobiology of near- and long-term consequences of single and repeat concussion and its epidemiology particularly in sports. Major challenges in the field include the need for improved accuracy of diagnosis in real-time, biomarker-based assessments to better determine objective metrics of recovery, and personalized risk assessment for recurrent injury.

Definition

Concussion is a mild TBI defined by a typically transient appearance of neurologic signs and symptoms, including headache, dizziness, imbalance, tiredness and fatigue, light and sound sensitivity, concentration difficulties, and memory impairment (often described as a brain "fog"), sleep disturbance, or mood disorder, following either a direct or an indirect rapid movement in the brain causing extreme rotational or translational brain acceleration or deceleration injury. Loss of consciousness at the time of impact is not required to make a diagnosis of concussion. Additional symptoms of the time of impact may include transient visual disturbances or spontaneous visual hallucinations, commonly described to "seeing stars." A related term, *subconcussive brain injury*, is also a mild TBI, often with the same underlying cause or etiology of concussive injury, but without any signs or symptoms.

Concussion can occur by any traumatic etiology including falls from a sufficient height, motor vehicle accidents, nonpenetrating blast injuries in the field of combat, domestic violence, or other physical traumatic events. *Sport-related concussion* (SRC) is defined as a concussion that occurs coincidentally during the play of a contact sport with a high risk of concussion (ie, American football, soccer [European football], hockey, lacrosse, basketball, wrestling, and rugby, among others) or during combat sports, which are distinguished by having the specific goal of inducing a concussion in the opponent (boxing, mixed martial arts, and related sports). Regardless of the etiology of concussion, the symptoms are largely indistinguishable but may have differing psychosocial factors associated with recovery.

In contrast to other more advanced forms of TBI, concussion lacks defining neuroradiologic features such as hemorrhage or other obvious abnormalities on conventional neuroimaging such as computed tomography (CT) or magnetic resonance imaging (MRI). Although imaging biomarkers including high-field MRI sequences such as diffusion tensor imaging and functional MRI, fluid-based biomarkers and electroencephalogram approaches are currently under study, none is presently used

in part of standard of care practice for the diagnosis of concussion or subconcussive injuries. Given substantial differences in these MRI sequences between individuals, the comparison of an individual against normative values has substantial limitations and thus currently limits the use of diffusion tensor imaging and functional MRI principally to research rather than clinical practice.

Epidemiology

The substantial degree of heterogeneity in TBI has made determining its epidemiology difficult. No two injuries are alike, person to person, or even within a single individual with multiple concussions. Other differences in each injury include mechanism of injury, forces applied to and head kinematics of the injured person, the location of injury, the context in which the injury occurred, as well as the likelihood of reporting symptoms. The lifetime incidence of single and repeat concussion is not well-known but is thought to occur in several million individuals annually in the United States alone. The epidemiology follows a trimodal pattern over lifetime with peaks in the first few months of life, followed by adolescence, and followed by a third peak in the elderly. Contributions to concussion etiology among the very young and very old likely principally relate to accidental falls, whereas concussions in adolescents is related to risk-taking behaviors involving driving, exposure to violence, as well as exposure to increasingly competitive athletics.

Although SRC comprises only a small fraction of all concussions, SRC offers the opportunity for more clearly establishing its epidemiology, symptomatology, and recovery timelines given relatively contained systems in place for monitoring athletes, particularly at the collegiate level. The annual incidence of SRC is at least 300,000 in the United States alone, although this is likely an underestimate given poor recognition by affected players. The epidemiology of recurrent concussion is not well described but is thought to happen in a small proportion of players previously affected by SRC who may be at subsequent greater risk. Factors leading to recurrent concussion are not well-known and may relate to ongoing exposure to sports at high risk for contact and collision.

Pathobiology

Given that concussion patients generally have no evidence of structural brain injury using conventional neuroimaging with MRI or CT, concussion has historically been considered a physiologic alteration, but this has become a matter of some debate. Concussion may reflect substantial physiologic disturbance with significant microstructural axonal disruption, which remains difficult to detect but nonetheless occurs. These injuries may be widespread or alternatively relatively focal but involving pathways with major widespread clinical implications. Experimental models suggest metabolic changes including elevated tissue lactate, which peaks over the course of several days followed by gradual recovery of cerebral blood flow within the affected tissues, with most demonstrable changes resolving by 7 to 10 days. In response to rotational or translational shear physical stress, animal histopathologic models of concussion demonstrate disruption of the viscoelastic properties of axons with rare disruption or lysis of axons themselves (**Fig. 46.1**).

When considering an individual experiencing a single concussion, injury thresholds required to cause concussion are not well understood but are thought to occur following at least 60 g of linear acceleration or at least 2,000 to 4,000 rad/s^2 rotational acceleration; these forces are seldom if ever experienced in the course of normal daily life outside of recognized physically traumatic events experienced by the affected individuals. At present, risks for concussion occurrence, severity, and recurrence are not well understood but suggest prior TBI raises the risk of subsequent concussion. The highly variable nature of concussion expression and recovery raises the possibility of an unrecognized gene-environment risk profile.

FIGURE 46.1 Human brain deformation including prediction by finite element simulation in response to a rotational acceleration of the head. Coronal sections. **A:** Finite element model, resting state. **B:** Conceptualized model of a human brain deformation in coronal plane. **C:** Finite element simulation in response to rotational acceleration. A linear force (impact) from the right side of the image would cause brain deformation shown in **B** and **C**, due to regional brain acceleration and not direct force of the skull on adjacent brain. The direction of resultant brain rotational acceleration is counter clockwise with the center of the brain lagging behind the outer regions closer to the skull. Deformation model shown is sufficient to induce severe traumatic brain injury; mild traumatic brain injury deformations are less dramatic. (Courtesy of Barclay Morrison, Professor of Biomedical Engineering, Columbia University.)

Diagnosis

Concussion experienced in nonsports contexts, such as motor vehicle accidents or other causes of trauma, is often diagnosed at the time that the individual is brought to attention for other matters related to bodily or head trauma. Although many concussion screening rubrics have been proposed, fundamentally, the diagnosis is based on a clinician's suspicion that concussion has occurred based on neurologic symptoms and that a more serious form of TBI has not occurred. In concussion, there should be no significant focal neurologic findings on examination. Any localizing or lateralizing signs or symptoms should prompt a clinician to consider neuroimaging, such as CT if the patient is suspected of having urgently declining neurologic condition or MRI if the patient is being assessed in a nonurgent setting or experiencing unexpectedly prolonged recovery of signs or symptoms following injury.

A number of devices and tools have been suggested to comprise concussion monitoring strategies, including questionnaires, complemented by a range of tests from simple reaction time to automated neuropsychological testing to more formal/conventional neuropsychological testing. Aside from symptom inventories and cognitive screening, initial and subsequent clinical exams following concussion should specifically focus on balance and eye movements. Balance assessments can include conventional assessments of gait and station, but more sensitive tests including tandem station and single foot stance may be further revealing of subtle balance problems. Moreover these can be tracked in the office and by the patient over time to monitor recovery. Extraocular movement abnormalities may include spontaneous or provoked nystagmus, saccadization of pursuits and overshoot of distal targets, impaired convergence, and impaired suppression of the vestibulo-ocular response. These can often be identified on clinical examination; formal assessment of extraocular movements may be useful in subtle or refractory cases, especially if misalignment is suspected. Accompanying TBI may be other sequelae of the same injury mechanism, including benign paroxysmal positional vertigo, whiplash injury, and focal traumatic cranial neuropathies.

In the special case of SRC, in recent years, a more conservative approach to care has involved youth, collegiate, and professional sports. Broadly speaking, aims have shifted toward early recognition of injury (including on the field or sideline), removal from play when concussion has been suspected, and no return to play until medically cleared. Legal statutes dictate this approach in youth sports in all 50 states, and conference/league policies now take a similar approach in collegiate and professional levels. Once the athlete has been removed from play, the approach to diagnosis is similar to that of other persons with concussion, although some tools have been developed specifically for sports. Current consensus guidelines advocate the use of a standardized screening assessment, such as the Sideline Concussion Assessment Tool (fifth version) in the context of game play, but the validity of this and other screening tools in clinical contexts remain uncertain, and a comprehensive neurologic assessment should be pursued whenever concussion is suspected.

With the exception of formal neuropsychological testing, which has a significant disadvantage as a screening tool given its cost and time required, most if not all, other tests in this field were developed as tools to assist in sideline assessments by nonmedical staff, with the intention of screening to limit the risk of prematurely returning a player to contact sport. Thus, they must be interpreted with some caution and cannot supplant formal neurologic evaluation, which may capture subtleties not otherwise recognized on these screening assessments. Moreover, some screening assessments are considered normal within a relatively large range of values, are prone to baseline errors and retest bias, and may have limited generalizability beyond a relatively small reference population of youth and young adult athletes. Finally, most tests used in serial concussion monitoring programs are susceptible to "gaming" or "sandbagging" by a player eager to return to play, with baseline assessments purposefully performed poorly such that postconcussion assessments may not substantially differ.

Management

At present, there are no rigorously studied or U.S. Food and Drug Administration–approved medical therapies or physical therapy treatments, which have been clearly proven to hasten recovery following a single concussion or improve lingering postconcussion symptoms. Empiric approaches to concussion treatment among non-SRC are based on approaches developed for SRC recovery. For SRC, guidelines recommend at least 24 hours removal from contact sport following any suspected concussion. Thereafter, players experience a graduated, patient-centered return-to-play protocol beginning with slow introduction of aerobic, followed by anaerobic exercise leading into full contact drills. In the past, "cocoon therapy," or prolonged rest and removal from any potentially cognitively or physically engaging scenarios, was suggested but is now thought to not only not work but may even delay recovery or make patients worse. Instead, symptom-limited engagement in physical, cognitive, and social activities should be resumed as early as possible and in a graduated manner. Recovery from concussion of any kind typically takes place over the course of at least a week following a suspected concussion, predicated on a player not reexperiencing symptoms of concussion as each threshold of activity is gradually approached. In the case of an athlete, only when a player is symptom-free and off all medications potentially providing a clinical advantage or benefit (including those used for pain relief) is the player considered to have recovered from a concussion.

Although much attention has historically been paid to reengaging an athlete in their sport, return to academic activity in student-athletes is of high priority. The process of engaging the injured student, their school, and parents in academic and other scholarly activities involves a multimodal treatment approach referred to as *return to learn*. Youth athletes should have completed their return to learn process with full recovery before cleared to return to sports at high risk for contact/collision or other high-risk activities. At each point of contact with a young individual having experienced concussion, clinicians should attempt to assess the player's current level of stamina for athletic and/or cognitively stimulating activities as well as potentially aggravating symptoms such as screen time in the course of computer or cellular telephone use typically used in social and academic settings. These guidelines provide a tool to monitor progress and encourage the individual to be an active participant in the recovery. Approaches to patients affected by concussion in nonsport contexts should follow similar threshold-based, gradual, patient-centered approaches to return to work, social, and professional life. Psychological support, at the same time as supporting physiologic recovery from concussion, can be a

key element of treatment in both children and adults, who may perceive that they are falling behind in their personal, social, and academic goals. Engaging the patient, family, school, or work may be helpful in setting shared expectations of recovery and support of the individual along the course of recovery.

Retirement from sport or a risky behavior associated with recurrent concussions in an individual may be considered in some scenarios; in the context of SRC, this concept is called *medical retirement* or *medical disqualification from sport*. Such a discussion is done in a highly individualized and often challenging manner, balancing factors of patient and family motivation, potential scholarship, or other fiscal incentive to continue playing against an uncertain and highly variable neurologic prognosis. However, this may be an appropriate decision among players who demonstrate progressively lower thresholds of injury required to express concussion; progressively longer neurologic recovery periods following successive concussions; and declining scholarly, neuropsychological, or athletic performance.

Outcome

The natural history of a single uncomplicated concussion is not well understood. Based on SRC studies of high school and collegiate athletes involved in contact sports, approximately 80% to 90% of all persons with single uncomplicated concussions will fully recover within several days to 2 weeks. In the short term, approximately 10% to 20% of individuals with concussion will have a prolonged recovery—longer than 1 to 2 weeks and occasionally up to several months. Symptoms lingering beyond this time frame raise the possibility of a preexistent or superimposed neuropsychological condition including a mood disorder or premorbid migraine headaches. Some studies have suggested that recurrent concussions portend to a more prolonged recovery, with decreasing threshold of injury in some being associated with subsequent concussion.

Following head trauma of any kind, including concussion, patients may be more likely to express migraine headaches, mood disorders, or benign paroxysmal positional vertigo, given the likely contribution of the impact to canalithiasis. At present, no evidence exists to treat these individuals any differently than would a patient be treated with these diagnoses as primary or nontraumatic disorders. However, some patients experiencing several lingering symptoms or syndromes may be best served by using therapies, which offer treatment impact in multiple modalities through a relatively simple regimen. Some evidence of nonsport mild TBI suggests that social, interpersonal, and professional repercussions of TBI may be more apparent in the long term even after objective cognitive deficits have resolved. Those engaging in early care and support may be able to address emerging behavioral and interpersonal issues, which can begin to emerge around the time of objective neurologic recovery but before full return to social, academic, and professional routines.

The long-term risks and outcomes associated with single uncomplicated concussion are not well-known, and large epidemiologic studies have found inconsistent relationships in clinical and pathologic outcomes. Studies of apolipoprotein E4 are limited but have not identified differences in concussion risk or recovery based on carrier status. Although single uncomplicated concussion is considered a mild TBI, recurrent concussions have been associated with significantly increased likelihood of developing major neuropsychiatric disorders associated with aging, including depression, dementia, Parkinson disease, amyotrophic lateral sclerosis, and erratic psychosocial behaviors including drug abuse and suicide, thus significantly impacting the quality of life of many affected individuals and their families.

One reason for the mandatory removal from play for a suspected concussion and graduated return to play thereafter is based on concern for a rare yet clearly defined neurologic syndrome called *second impact syndrome*. The disease has been identified exclusively among individuals who have returned to sports or had a second concussion prior to complete recovery from the first concussion, even if the two events are separated by days. The pathophysiology of second impact syndrome is not well understood but appears to involve severe, aggressive, and often medically refractory focal or whole brain edema following the second concussion.

CHRONIC TRAUMATIC ENCEPHALOPATHY

Introduction

Chronic traumatic encephalopathy is a term used to describe the long-term neurodegenerative pathology that arises following repetitive concussions (ie, mild TBI). Chronic traumatic encephalopathy (CTE) was initially termed *punch drunk* and later *dementia pugilistica* in light of its long-established association with boxing. The CTE can arise in any individual with repetitive concussive or subconcussive injuries (eg, victims of domestic violence and autistic patients with head-banging behavior), but athletes who have participated in contact and/or combat sports have received the most attention. Military veterans represent another at-risk population that has been increasingly studied. Furthermore, some veterans with a clinical diagnosis of posttraumatic stress disorder have been found to have CTE at autopsy, suggesting a potential overlap between these conditions. The diagnostic hallmark is accumulation of abnormal hyperphosphorylated tau protein in a distinct neuroanatomic distribution that clearly differentiates it from other neurodegenerative diseases and aging.

Epidemiology

The epidemiology of CTE is not well established given the lack for formalized diagnostic clinical criteria, some similarities with other sporadic neurodegenerative diseases. Some pathologic studies suggest coexpression of CTE with other pathologies, including Alzheimer disease, Lewy body diseases, and cerebral amyloid angiopathy, is common, and TBI exposure may make these other copathologies more severe. As is the case in degenerative cognitive disorders, clinical features may incompletely track with pathologic findings, including presence and severity of CTE and related pathologies. This is even so in known high-risk combat sports such as boxing where to date, only case series have been published, followed by more recent series involving participants in contact sports such as football, hockey, baseball, and soccer as well as combat military veterans. Case reports also exist among domestic violence victims. A recent case series of professional football players from a highly selected population of families and individuals concerned about major neurobehavioral

changes identified CTE in the vast majority of subjects. Despite potential for bias, for all known professional American football brain autopsies among the published 110 cases published as of 2017 coincided with approximately 1,300 known deaths over the same time frame. Thus, a minimum of 8.5% had neuropathologic-defined CTE at death. An expanded autopsy cohort suggested a dose dependence between years of professional football and both CTE risk and severity. Several young football players with neuropathologically defined early-stage CTE, who died for unrelated causes, have had no recognizable neurologic or psychiatric symptoms. However, a growing concern is that it may have substantial clinical sequelae when advanced neuropathologic changes are present. To date, the disease has not been recognized in the absence of head trauma, although the threshold of risk (how much and how severe injury is required to cause CTE) remains uncertain. Also, whether a single TBI can trigger CTE is not known.

Pathobiology

The pathogenesis of CTE is currently under investigation. Physical trauma is thought to lead to mechanical stress in the acute setting, shearing cellular structures (eg, axons, dendrites, synaptic connections, glial processes, and blood vessels), resulting in cognitive impairment, or postconcussive syndrome. Associated molecular changes with acute trauma include elevation of amyloid precursor protein and other proteins. Repetitive injury may progress to neurodegeneration, sometimes many years later. Gross brain changes are nonspecific but include brain atrophy and a cavum septum pellucidum. Microscopically, CTE patients exhibit marked accumulation of abnormal aggregates containing hyperphosphorylated forms of the microtubule-associated protein tau. Tau pathology is present in neurons and glia, leading to some diagnostic confusion at autopsy, especially in older patients who may have comorbid primary age-related tauopathy or aging-related tau astrogliopathy. Importantly, the pattern of tau pathology in CTE is distinct, with accentuation in mechanically vulnerable brain regions, including the neocortical sulcal depths and perivascular regions, which is pathognomonic (Fig. 46.2). The CTE as a sole pathology may be more likely discovered among younger persons with a history of recurrent TBI exposure. As many as 85% of CTE patients also exhibit accumulation of 43 kDa TAR DNA–binding protein, the primary disease protein in amyotrophic lateral sclerosis. Amyloid plaques that are characteristic of Alzheimer disease and α-synuclein–positive inclusions of Parkinson disease can also be observed. Additional findings are diverse, including subcortical axonal varicosities and axonal loss.

Diagnosis

The proposed clinical correlate of CTE has been termed *traumatic encephalopathy syndrome* (TES) and is associated with a spectrum of personality and behavioral changes, depression, increased suicidal behavior, memory loss, and cognitive dysfunction. The clinical spectrum of TES is broad, and the full extent of the symptomatology awaits larger autopsy series, but recent research suggests that TES has two clinical variants. The first is a *behavioral/mood variant* with features that develop at a younger age. The other is a *cognitive variant* that arises at an older age. Movement disorders, including parkinsonism, are also common. Proposed criteria for TES are provided in **Table 46.1**.

Furthermore, it is not uncommon to observe motor neuron disease in CTE patients; this had been referred to as *chronic traumatic encephalomyelopathy*, but this term has fallen out of favor. Dementia, parkinsonism, and motor neuron disease can occur singly or collectively in a single patient. Cognitive decline may be similar clinically to Alzheimer disease or frontotemporal dementia and the approach to the patient presenting with TES should involve the diagnostic approach taken in diagnosing other neurodegenerative disorders. A TES can serve as an alternative explanation to atypical presentations of neurodegenerative cognitive disorders but remains a diagnosis of exclusion at present. Most CTE cases are thought to progress over decades. Manifestations of neurologic decline typically begin years after cessation of exposure to high-risk sports or recognized head injury, although some athletes have quit after developing chronic cognitive problems in the context of ongoing competitive play. Whether these changes signal active clinical manifestations of CTE is of great debate because no validated in vivo biomarkers currently exist.

FIGURE 46.2. Regional vulnerability following traumatic brain injury. **A:** Contusions can be demonstrated grossly in the depths of the neocortical sulci after acute traumatic brain injury *(arrowheads)*. **B:** Immunohistochemistry using antisera that specifically target abnormal hyperphosphorylated tau (p-tau) reveals a predilection for the neocortical sulci *(arrowheads)* in a retired professional football player with chronic traumatic encephalopathy. **C:** Photomicrograph of a brain section from the cortex of a patient with chronic traumatic encephalopathy showing p-tau immunostain-positive neurons *(brown)* surrounding a blood vessel *(arrow)*. The section is counterstained with hematoxylin *(blue)*. (**B** courtesy of Dr. Ann McKee, Boston University.)

TABLE 46.1 Diagnostic Criteria for Traumatic Encephalopathy Syndrome[a]

Required Features	Supportive Features
Persistence of symptoms for longer than 2 y	Emotional dysregulation including depression, anxiety, agitation, aggression, paranoid ideation, deterioration of interpersonal relationships, and suicidality
Absence of another neurologic disorder that is more likely to account for all the clinical features	Behavioral change including violence, poor impulse control, socially inappropriate behavior, avolition, apathy, change in personality, and comorbid substance abuse
History of head trauma exposure, typically associated with history of concussion, although may be limited to subconcussive trauma Head trauma exposure is repetitive in nature Progressive course Delayed symptom onset Self-report or observer report of cognitive dysfunction, typically affecting more than one domain, confirmed with objective cognitive decline documented by results of formal neuropsychological testing	Motor disturbance including bradykinesia, tremor, rigidity, gait instability, dysarthria, dysphagia, ataxia, and gaze disturbance
Criteria for Diagnosis	
Possible TES: requires history of head trauma exposure, persistence of symptoms for longer than 2 y, no other neurologic disorder that is more likely to account for all the clinical features, progressive course, and at least one supportive feature.	
Probable TES: meets the criteria of possible TES plus history of traumatic impact exposure that is repetitive in nature, delayed symptom onset, cognitive decline, and at least one supportive feature.	
Unlikely TES would not meet minimum diagnostic criteria for possible TES and may include individuals in whom another neurodegenerative disease or psychiatric disorder is likely.	

Abbreviation: TES, traumatic encephalopathy syndrome.
[a]Adapted from Reams N, Eckner JT, Almeida AA, et al. A clinical approach to the diagnosis of traumatic encephalopathy syndrome: a review. *JAMA Neurol.* 2016;73(6):743-749.

Management

The care of patients with a history TBI and possible or probable TES should involve an individualized care plan, tailored toward supporting the specific cognitive, behavioral, motoric, and functional challenges faced by the patient and their caregivers. No specific therapies are available for the treatment of TES once symptoms develop. Prevention measures include harm reduction strategies related to both TBI and other adverse outcomes.

Outcome

Several longitudinal clinical studies of high-risk athletes are underway, including professional and amateur American football and international soccer players. Based on mortality studies, it is suggested that exposure to professional American football or international soccer is associated with higher rate of death due to dementia or amyotrophic lateral sclerosis, and possibly Parkinson disease, relative to the causes of death among controls or the general population. Notably, these athletes experience lower mortality rates overall and have lower rates of death due to cardiovascular disease or cancer. The natural history of TES and CTE remains uncertain.

In American football, a cumulative head impact index has been proposed to identify thresholds of lifetime exposure to recurrent head impacts and possible inflection points increasing the risk of behavioral and cognitive outcomes as well as biomarker-based changes in later adulthood. Suicide has emerged as a cause of death among several former elite athletes, including in a period prior to recently increased CTE awareness, yet its epidemiology is not well understood. Although high-risk sports may portend to slightly higher risk of suicide in college athletes during the period of activity, studies of American football have suggested lower risks of suicide than the general U.S. population, perhaps related complex factors associated with playing professional sport.

Finally, given the distinctly known and highly preventable risk factor of head injury leading to concussion and presumably CTE in combat sports and perhaps also in contact sports, a substantial ethical and moral dilemma is raised by this spectrum of disease. Although many professional groups, including neurologists, have advocated for banning boxing, most likely public interest in these sports will persist. Historical accounts suggest an increased risk of death during time periods when sports like these are banned yet persist in an underground or unsanctioned manner without the involvement of neurologists or colleagues in supervision or consultation. At present, there are no personalized models of neurologic risks of high-risk sports yet the appetite of the general public for such sports remains high. Neurologists have an important role in shaping public knowledge of combat and high-risk contact sports, navigating the understanding and uncertainty of near- and long-term risks for the individual athlete and supporting the inherent benefits of exercise and athleticism.

Traumatic Brain Injury 47

Gunjan Y. Parikh, Neeraj Badjatia, and Stephan A. Mayer

KEY POINTS

1. Traumatic brain injury (TBI) is a heterogeneous group of pathologic disorders that can be categorized by mechanism of injury, clinical severity, radiologic appearance, pathology, or anatomic distribution.
2. TBI endophenotypes other than axonal injury include vascular injury and an exaggerated inflammatory response.
3. The epidemiology of TBI is trimodal with accidents and falls occurring in early and late life and accidents associated with road travel and risk-taking activities most common in early and mid-adulthood.
4. Coordinated systems of care are crucial for optimal TBI management, but inconsistencies in implementation occur in all phases along the chain of trauma care.
5. In TBI, patient-centered treatment strategies may not always align with generalized guidelines, which encompass a wide range of injury type and severity.
6. TBI is a chronic, progressive health condition. Secondary injury continues to occur for days to weeks after primary insult secondary to innate host response to injury.
7. Functional outcomes after TBI can show improvement or deterioration up to two decades after injury, and rates of all-cause mortality remain elevated for many years.
8. TBI is an important modifiable risk factor for epilepsy, stroke, and late-life neurodegenerative disease.

EPIDEMIOLOGY

Traumatic brain injury (TBI) is a modern scourge of industrialized society. It is a major cause of death, especially in young adults, and a major cause of disability. The costs in human misery and dollars are exceeded by few other conditions.

More than 2.8 million patients with head injuries are seen annually in U.S. emergency rooms, and 10% of these patients are admitted to a hospital. In general, total combined rates for TBI-related emergency department (ED) visits, hospitalizations, and deaths have increased over the past decade. Almost 10% of all deaths in the United States are caused by injury, and about half of the traumatic deaths involve the brain. In the United States, a head injury occurs every 7 seconds and a death every 5 minutes. About 200,000 people are killed or permanently disabled annually as a result. Worldwide, more than 50 million people have a TBI each year, and it is estimated that half the world's population will sustain one or more TBI over their lifetime. A disproportionate burden of disability and death occurs in low-income and middle-income countries. It has been estimated that TBI costs the global economy more than $400 billion annually.

Brain injuries occur at all ages, but the peak is in young adults between the ages of 15 and 24 years. Head injury is the leading cause of death among people younger than the age of 24 years. Men are affected 3 or 4 times as often as women. The major causes of brain injury differ in different parts of the United States; in all areas, motor vehicle accidents are prominent, and in metropolitan areas, personal violence is prevalent. There is, however, a trend toward an increase of mortality rates from TBI among populations aged older than 65 years over the past decade. It is anticipated that this trend will continue as the overall population ages. Among older adults, the most prevalent mechanism of injury is falls, and TBIs occur more commonly in women.

PATHOBIOLOGY

Skull Fractures

Skull fractures may be divided into linear, depressed, or comminuted types. If the scalp is lacerated over the fracture, it is considered an open or *compound fracture*. Skull fractures are important markers of a possibly serious injury but rarely cause problems by themselves; prognosis depends more on the nature and severity of injury to the brain than on the severity of injury to the skull.

About 80% of fractures are linear. They occur most commonly in the temporoparietal region, where the skull is thinnest. Detection of a linear fracture often raises the suspicion of serious brain injury, but computed tomography (CT) in most patients is otherwise normal. Nondisplaced, linear skull fractures generally do not require surgery and can be managed conservatively.

In *depressed* fracture of the skull, one or more fragments of bone are displaced inward, compressing the underlying brain. In comminuted fracture, there are multiple, shattered bone fragments, which may or may not be displaced. In 85% of cases, depressed fractures are open (or "compound") and liable to become infected or leak cerebrospinal fluid (CSF). Even when closed, most depressed or comminuted fractures require surgical exploration for debridement, elevation of bone fragments, and repair of dural lacerations. The underlying brain is injured in many cases. In some patients, depressed skull fractures are associated with tearing, compression, or thrombosis of underlying venous dural sinuses.

Basilar skull fractures may be linear, depressed, or comminuted. They are frequently missed by standard skull x-rays and are best identified by CT bone windows. There may be associated cranial nerve injury or a dural tear adjacent to the fracture site, which may lead to delayed meningitis if bacteria enter the subarachnoid space.

Signs that lead the physician to suspect a fracture of the petrous portion of the temporal bone include hemotympanum or tympanic perforation, hearing loss, CSF otorrhea, peripheral facial nerve weakness, or ecchymosis of the scalp overlying the mastoid process (Battle sign). Anosmia, bilateral periorbital ecchymosis, and CSF rhinorrhea suggest possible fracture of the sphenoid, frontal, or ethmoid bones.

Cerebral Concussion and Axonal-Shearing Injury

Concussion is defined as a mild TBI without obvious structural abnormality identified on standard neuroimaging. Loss of consciousness may occur at the moment of impact in about 10% to 15% of concussion and is thought to be caused by acceleration-deceleration movements of the head, which result in the stretching and, in some cases, shearing of axons. Persons with concussion may be completely unconscious or remain awake but appear dazed; most recover within seconds or minutes, rather than hours, and some have retrograde or anterograde amnesia surrounding the event. Concussion is reviewed in further detail in Chapter 46.

The mechanism by which concussion leads to loss of consciousness is believed to be transient functional disruption of the reticular activating system caused by rotational forces on the upper brainstem. Experimentally, sudden and violent head rotation may produce concussion without impact to the head. Most patients with concussion have normal CT or magnetic resonance imaging (MRI) findings because concussion results from physiologic, rather than structural, injury to the brain. Only 5% of patients who have sustained a concussion and are otherwise intact have an intracranial hemorrhage on CT, although this figure may be biased toward persons presenting to EDs. In some series of adolescent sports-related concussion, detection of intracranial hemorrhage may be less than 1 in 1,000.

The term *diffuse axonal injury* (DAI) is applied to traumatic coma lasting more than 6 hours. In these cases, when no other cause of coma is identified by CT or MRI, it is presumed that widespread microscopic and macroscopic axonal-shearing injury has occurred. Coma of 6 to 24 hours duration is deemed mild DAI; coma lasting more than 24 hours is considered moderate or severe DAI, depending on the absence or presence of brainstem signs, such as decorticate or decerebrate posturing (**Table 47.1**).

Autonomic dysfunction (eg, hypertension, hyperhidrosis, hyperpyrexia) is common in patients with acute severe DAI and may reflect brainstem or hypothalamic injury. Patients may remain unconscious for days, months, or years, and those who recover may be left with severe cognitive and motor impairment, including spasticity and ataxia. DAI is considered the single most important cause of persistent disability after traumatic brain damage.

Axonal shearing injury tends to be most severe in specific brain regions that are anatomically predisposed to maximal stress from rotational forces. Macroscopic tissue tears, best visualized by MRI, tend to occur in midline structures, including the dorsolateral midbrain and pons, posterior corpus callosum, parasagittal white matter, periventricular regions, and internal capsule. Microscopic damage occurs more diffusely, as manifested by axonal retraction bulbs throughout the white matter of the cerebral hemispheres. TBI endophenotypes other than axonal injury include vascular injury and an exaggerated inflammatory response (**Fig. 47.1**). Prolonged loss of consciousness from DAI tends to be associated with bilateral, asymmetric, focal lesions of the dorsal tegmentum of the pons and midbrain, a region densely populated with brainstem nuclei of the ascending arousal network that are critical to consciousness (**Fig. 47.2**). Small hemorrhages, known as *traumatic microbleeds*, are sometimes associated with focal-shearing lesions (see **Fig. 47.1**; **Fig. 47.3**).

Axonal shearing is thought to initiate a dynamic sequence of pathologic events that evolve over days to weeks. Initially, injury causes physical transection of some neurons and internal axonal damage to many others. In both cases, the process of axoplasmic transport continues, and materials flow from the cell body to the site of damage. These materials accumulate and may lead to secondary axonal transection, with formation of a "retraction ball" from 12 hours to several days after the injury. Membrane channels may open to admit toxic levels of calcium. If the patient survives, MRI may demonstrate chronic atrophy of involved white matter tracts (wallerian degeneration) and gliosis.

TABLE 47.1 Clinical Characteristics and Outcome of Rotational Brain Injury[a]

	Concussion			Diffuse Axonal Injury		
	Grade 1	Grade 2	Grade 3	Mild	Moderate	Severe
Loss of consciousness	None	<5 min	>5 min	6-24 h	>24 h	Days to weeks
Memory deficit and amnesia	Minutes	Hours	Days	Days to weeks	Weeks	Months
Motor posturing	None	None	None	Rare	Occasionally	Present
Chronic motor deficits	None	None	None	None	Mild-to-moderate	Severe
MRI shearing lesions	None	None	None	None	Few and variable	Multiple and extensive
Outcome at 3 mo (%)						
Good recovery	100	95	90	80	70	20
Moderate deficit	0	5	5	20	20	25
Severe deficit	0	0	5	0	15	15
Vegetative	0	0	0	0	0	5
Death	0	0	0	0	5	35

[a]Data from Gennarelli TA. Cerebral concussion and diffuse brain injuries. In: Cooper PR, ed. *Head Injury*, 3rd ed. New York, NY: Williams & Wilkins; 1993:140; Iverson GL, Gardner AJ, Terry DP, et al. Predictors of clinical recovery from concussion: a systematic review. *Br J Sports Med*. 2017;51(12):941-948; Humble SS, Wilson LD, Wang L, et al. Prognosis of diffuse axonal injury with traumatic brain injury. *J Trauma Acute Care Surg*. 2018;85(1):155-159.

FIGURE 47.1 Traumatic vascular injury. Traditionally, traumatic microbleeds have been described as markers for diffuse axonal injury, not as a form of traumatic vascular injury. However, magnetic resonance imaging (MRI) and three-dimensional histology identified an underlying pathology of traumatic microbleeds to be an injury to not just a single vessel but injury that extends to a vascular network. Injury to a large blood vessel causes iron deposition that is detectable on in vivo and ex vivo MRI (at 3T and 7T). Smaller vessels that form a broader vascular network with the larger vessels are missed in these magnetic resonance images. High-resolution three-dimensional histology of iron deposits in macrophages identified more extensive vascular injury involving smaller vessels that connect to the larger injured vessel detected on MRI. The schematic above illustrates a model of this vascular injury pattern and potential levels of detection with MRI and histologic approaches. (From Griffin AD, Turtzo LC, Parikh GY, et al. Traumatic microbleeds suggest vascular injury and predict disability in traumatic brain injury. *Brain*. 2019;142[11]:3550-3564.)

FIGURE 47.2 Revisiting grade 3 diffuse axonal injury: Not all brainstem microbleeds are prognostically equal. Brainstem traumatic microbleeds (TMBs) detected by T2* gradient-recalled echo magnetic resonance imaging. A patient with a large cluster of hypointense lesions, representing TMBs, in the dorsal pons is shown in the **top panel**. A patient with two smaller ovoid TMBs in the dorsal pons is shown in the **bottom panel**. The patient whose gradient-recalled echo scan is shown in the **top panel** had a poor outcome, as evidenced by a high disability rating scale (DRS) score of 20. The patient in the **bottom panel** had a better outcome, with a DRS score of 8, indicating less functional disability. Notably, both patients had a total of four dorsal brainstem TMBs, but the patients had different burdens of injury within the ascending arousal network nuclei (104 vs 20 mm^3), which may explain the divergence in functional outcomes. (From Izzy S, Mazwi NL, Martinez S, et al. Revisiting grade 3 diffuse axonal injury: not all brainstem microbleeds are prognostically equal. *Neurocrit Care*. 2017;27[2]:199-207.)

FIGURE 47.3 Focal magnetic resonance imaging findings characteristic of diffuse axonal-shearing injury after neurotrauma. **Top:** Gradient echo images demonstrating hemorrhagic lesions (traumatic microbleeds) of the right dorsolateral midbrain and splenium of the corpus callosum. **Bottom:** Fluid-attenuated inversion recovery images showing edema in these regions.

Brain Swelling and Cerebral Edema

Brain swelling after head injury is a poorly understood phenomenon that may result from several different mechanisms. Posttraumatic brain swelling may result from *cerebral edema* (eg, an increase in the content of extravascular brain water), an increase in cerebral blood volume (CBV) resulting from abnormal vasodilatation, or both. Cerebral edema may be further classified as cytotoxic, vasogenic, or interstitial (see Chapter 111). The swelling may be diffuse or focal, adjacent to a parenchymal or extradural hemorrhage, or related to contusion or infarction.

Brain swelling may follow any type of head injury. Curiously, the magnitude of swelling does not always correlate well with the severity of injury. In some cases, particularly in young people, severe diffuse brain swelling that may be fatal occurs minutes to hours after a minor concussion. Abnormal dilation of the cerebral blood vessels is thought to lead to increased CBV, hyperperfusion, and increased vascular permeability, resulting in secondary leakage of plasma and vasogenic cerebral edema. Cerebral blood flow studies indicate that after an initial period of hypoperfusion within the first 24 hours, hyperemia occurs in nearly all patients 1 to 3 days after severe head injury, followed less commonly by arterial vasospasm between days 4 and 7. Severe brain swelling may be related to local endothelial and microcirculatory dysfunction or from damage to cerebral vasomotor regulatory centers in the brainstem.

Parenchymal Contusion and Hemorrhage

Cerebral *contusions* are focal parenchymal hemorrhages that result from scraping and bruising of the brain as it moves across the inner surface of the skull. The inferior frontal and temporal lobes, where brain tissue comes in contact with irregular protuberances at the base of the skull, are the most common sites of traumatic contusion (Fig. 47.4). Linear tears of the meninges or cerebral tissue, usually a result of cuts from the sharp edges of depressed skull fragments, are called *lacerations*.

Hemorrhagic contusions may occur at the site of a skull fracture but more often occur without a fracture and with the overlying pia and arachnoid left intact. In most patients, contusions are small and multiple. With lateral forces, contusions may occur at the site of the blow to the head (coup lesions) or at the opposite pole as the brain impacts on the inner table of the skull

FIGURE 47.4 Traumatic contusions. Axial noncontrast view demonstrates areas of contusion with small focal hemorrhages involving the lower poles of the left frontal and temporal lobes adjacent to the rough cranial vault. (Courtesy of Drs. S. K. Hilal, J. A. Bello, and T. L. Chi.)

FIGURE 47.5 Traumatic intracerebral hemorrhage, frontal lobe. Axial noncontrast computed tomography demonstrates left frontal lobe density (hemorrhage), surrounding lucency (edema), and mass effect (sulcal and ventricular effacement). (Courtesy of Drs. S. K. Hilal and J. A. Bello.)

(contrecoup lesions). Contusions frequently enlarge over 12 to 24 hours, especially in the setting of coagulopathy. In some cases, contusions appear in delayed fashion 1 or more days after injury.

When rotational forces lead to tearing of small- or medium-sized vessels within the parenchyma, an intracerebral *hematoma* may occur (Fig. 47.5). Hematomas are focal collections of blood clots that displace the brain, in contrast to contusions, which resemble bruised and bloodied brain tissue (Fig. 47.6). Most parenchymal hematomas are located in the deep white matter, in contrast to contusions, which tend to be cortical.

If there is no DAI, brain swelling, or secondary hemorrhage, recovery from one or more small contusions may be excellent. Healed contusions are often found at autopsy of people with no clinical evidence of permanent brain damage. Large, parenchymal hematomas with mass effect may require surgical evacuation.

Contusions are often managed conservatively unless they lead to significant symptomatic mass effect because they often consist of hemorrhagic or ecchymotic (but potentially viable) brain tissue.

Subdural Hematoma

Subdural hematomas usually arise from a venous source, with blood filling the potential space between the dural and arachnoid membranes. In most cases, the bleeding is caused by movements of the brain within the skull that leads to stretching and tearing of "bridging" veins that drain from the surface of the brain to the dural sinuses.

Most subdural hematomas are located over the lateral cerebral convexities, but subdural blood may also collect along the medial surface of the hemisphere, between the tentorium and occipital lobe, between the temporal lobe and the base of the skull, or in the posterior fossa. CT usually reveals a high-density, crescentic collection across the entire hemispheric convexity (Fig. 47.7).

FIGURE 47.6 Pathologic specimen demonstrating traumatic contusions in the temporal lobes.

FIGURE 47.7 Acute subdural hematoma. Noncontrast axial computed tomography demonstrates a hyperdense, crescent-shaped, extra-axial collection showing mass effect (sulcal and ventricular effacement) and midline shift from left to right. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

Elderly or alcoholic patients with cerebral atrophy are particularly prone to subdural bleeding; in these patients, large hematomas may result from trivial impact or even from pure acceleration-deceleration injuries, such as whiplash. Coagulopathy, including the use of oral anticoagulants, is another important risk factor for subdural hematoma and is associated with increased mortality.

Acute subdural hematomas, by definition, are symptomatic within 72 hours of injury, but most patients have neurologic symptoms from the moment of impact. They may occur after any type of head injury but seem to be less common after vehicular trauma and relatively more common after falls or assaults. Half of all patients with an acute subdural hematoma lose consciousness at the time of injury; 25% are in coma when they arrive at the hospital, and half of those who awaken lose consciousness for a second time after a "lucid interval" of minutes to hours as the subdural hematoma grows in size. Hemiparesis and pupillary abnormalities are the most common focal neurologic signs, each occurring in one-half to two-thirds of patients. The usual picture is ipsilateral pupillary dilation and contralateral hemiparesis. However, so-called false localizing signs are common with acute subdural hematoma because uncal herniation may lead to compression of the contralateral cerebral peduncle or third cranial nerve against the tentorial edge (*Kernohan notch*).

Chronic subdural hematomas become symptomatic after 21 days. They are more likely to occur in patients after age 50 years. In 25% to 50% of cases, there is no recognized episode of head injury. Risk factors for chronic subdural hematomas include cerebral atrophy, alcoholism, bleeding disorders or use of anticoagulant medication, and overdrainage of a ventriculoperitoneal shunt.

In many cases of chronic subdural hematoma, bleeding results from trivial trauma, and symptoms are minimal because the brain accommodates the gradual buildup of mass effect. After 1 week, fibroblasts on the inner surface of the dura form a thick outer membrane; after 2 weeks, a thin inner membrane develops, resulting in encapsulation of the clot, which eventually liquefies into a *hygroma*. Enlargement of the hematoma may then result from recurrent bleeding (acute-on-chronic subdural hematoma) or because of osmotic effects related to a high-protein content of the fluid. Symptoms may be restricted to altered mental status, a syndrome sometimes mistaken for dementia. CT typically shows an isodense or hypodense, crescent-shaped mass that deforms the surface of the brain, and the membranes may enhance with intravenous (IV) contrast (Fig. 47.8).

Symptomatic acute and chronic subdural hematomas with significant mass effect should be evacuated. Surgical evacuation of the thick, clotted blood that constitutes an acute subdural

FIGURE 47.8 Bilateral chronic subdural hematoma. **A:** Noncontrast axial computed tomography shows bilateral isodense extra-axial collections, larger on the left. **B:** These are better demonstrated on the postcontrast scan, in which enhancing membranes, typical of the subacute phase, may be seen. (Courtesy of Drs. J. A. Bello and S. K. Hilal.)

hematoma usually requires a large-window craniotomy. Outcome after surgical evacuation depends primarily on the severity of the initial deficit and the interval from injury to surgery. Liquefied chronic subdural hematomas are usually evacuated with drainage of the collections via a series of burr holes. Reoperations for acute and chronic subdural hematomas are required in about 15% of cases. Steroids have no role in the conservative management of smaller, minimally symptomatic, subdural hematomas.

Epidural Hematoma

Epidural hematoma is a rare complication of head injury. It occurs in less than 1% of all cases but is found in 5% to 15% of autopsy series, attesting to the potential seriousness of this complication.

Bleeding into the epidural space is generally caused by a tear in the wall of one of the meningeal arteries, usually the middle meningeal artery, but in 15% of patients, the bleeding arises from a dural sinus. Seventy-five percent of patients are associated with a skull fracture. The dura is separated from the skull by the extravasated blood, and the size of the clot increases until the ruptured vessel is compressed or occluded by the hematoma.

Most epidural hematomas are located over the convexity of the hemisphere in the middle cranial fossa, but occasionally, hemorrhages may be confined to the anterior fossa, possibly as a result of tearing of anterior meningeal arteries. Extradural hemorrhage in the posterior fossa may occur when the torcular herophili is torn. In most cases, the hematoma is ipsilateral to the site of impact.

Epidural hematoma is primarily a problem of young adults; it is rarely seen in the elderly because the dura becomes increasingly adherent to the skull with advanced age. The clinical course, in one-third of patients, proceeds from an immediate loss of consciousness caused by concussion to a lucid interval (representing a brief recovery from the concussion itself) and then to a relapse into coma, with hemiplegia as the epidural hematoma expands. The ipsilateral pupil loses reactivity to light because the third cranial nerve is stretched as the midbrain is displaced contralaterally. Later, it becomes fixed and dilated as the third nerve is compressed by the hippocampal gyrus as it herniates over the free edge of the tentorium.

As with acute subdural hematomas, false localizing signs may occur. The presence of cerebellar signs, nuchal rigidity, and drowsiness, together with a fracture of the occipital bone, should prompt suspicion of a clot in the posterior fossa.

Epidural blood takes on a bulging convex pattern on CT (Fig. 47.9) because the collection is limited by firm attachments from the dura to the cranial sutures. Progression to herniation and death may occur rapidly because the bleeding is arterial. The mortality rate approaches 100% in untreated patients and ranges from 5% to 30% in treated patients. As the interval between injury and surgical intervention decreases, survival improves. If there is little coexisting brain damage, functional recovery may be excellent.

Traumatic Subarachnoid Hemorrhage

Some extravasation of blood into the subarachnoid spaces is to be expected in any patient with head injury. In most cases, subarachnoid blood is detected only by CSF examination and is of little clinical importance. With more serious injuries, when larger vessels traversing the subarachnoid space are torn, focal or diffuse *subarachnoid hemorrhage* may be detected by CT. In most cases, traumatic subarachnoid hemorrhage is distributed over the convexities. By contrast, spontaneous aneurysmal rupture results in bleeding into the basal cisterns. Although the presence of a large amount of subarachnoid blood is a poor prognostic sign, delayed complications of aneurysmal subarachnoid hemorrhage, such as hydrocephalus and ischemia from vasospasm, are unusual after traumatic subarachnoid hemorrhage.

FIGURE 47.9 **A:** Epidural hematoma is evident on computed tomography. **B:** Computed tomography with bone windows shows two adjacent fractures *(arrows)*; the anterior fracture is at the site of the groove for the middle meningeal artery.

INITIAL ASSESSMENT AND STABILIZATION

On admission to the emergency room, resuscitation measures, history taking, and examination should begin simultaneously. The immediate goals of management are to assess and stabilize the airway, breathing, circulation, and disability. The immediate goals of the initial neurologic assessment are to (1) perform a rapid screening neurologic examination; (2) classify the severity of the head injury as low, moderate, or high risk; (3) stabilize and rule out a fracture of the cervical spine; (4) begin empiric treatment for increased intracranial pressure (ICP) if it is suspected; and (5) perform an emergency CT scan of the head and neck to rule out bony fractures or intracranial bleeding. Careful screening at this time is also required to identify significant extracranial injuries.

Cardiopulmonary Resuscitation

Hypoxia and *hypotension* have a devastating effect on head-injured patients. If the patient is hypoxic (arterial oxygen saturation level <90%), in respiratory distress, or comatose and unable to protect his or her airway, endotracheal intubation should be performed urgently to be certain that the spine is immobilized during the procedure. Two doses of peri-intubation cefuroxime (1.5 g) may reduce the risk of subsequent pneumonia. Minute ventilation should initially be set to maintain a tidal volume of 6 mL/kg and rate of 8 to 12 breaths per minute, with the goal of maintaining the P_{CO_2} between 30 and 40 mm Hg. The fraction of inspired oxygen can be quickly reduced from 100% to 40% as long as oxygen saturation levels are above 95%. Prophylactic aggressive hyperventilation (P_{CO_2} <25 mm Hg) during the acute stage of injury may cause excessive vasoconstriction and aggravation of ischemic injury and is contraindicated.

Hypotension (systolic blood pressure [BP] <90 mm Hg) should be corrected with large-volume IV infusions of isotonic fluids such as normal saline or lactated Ringer solution (10-40 mL/kg) and blood transfusions or vasopressors as needed. Systolic BP during the stabilization phase should be maintained above 90 mm Hg to ensure adequate cerebral blood flow. If the patient is hypotensive, bleeding into the abdomen, thorax, retroperitoneal space, or tissues surrounding a long-bone fracture should be excluded by CT. Hypotension may also reflect *spinal shock* related to a coexisting spinal cord injury (see Chapter 48). Hypertension associated with wide pulse pressure and bradycardia (Cushing reflex) may reflect increased ICP or focal brainstem injury.

Initial Neurologic Assessment and Stabilization

A baseline neurologic evaluation should be performed immediately while airway, respiration, and circulation are assessed. Injuries may be ranked as low, moderate, or high risk according to risk factors and a rapid initial neurologic assessment (Table 47.2). The skull should be palpated for fractures, hematomas, and lacerations. A step-off or palpable bony shelf is presumed to be a depressed skull fracture. A hard neck collar should be in place for all patients with any history of concussion, whiplash, or trauma above the level of the clavicles.

TABLE 47.2 Risk Stratification of Patients With Head Injury[a]

Risk Category	Characteristics
Mild	• Normal neurologic examination • No concussion • No drug or alcohol intoxication • May complain of headache and dizziness • May have scalp abrasion, laceration, or hematoma • Absence of moderate or severe injury criteria
Moderate	• Glasgow Coma Scale score of 9-14 (confused, lethargic, stuporous) • Concussion • Posttraumatic amnesia • Vomiting • Seizure • Signs of possible basilar or depressed skull fracture of serious facial injury • Alcohol or drug intoxication • Unreliable or no history of injury • Age <2 y, >65 y
Severe	• Glasgow Coma Scale score of 3-8 (comatose) • Progressive decline in level of consciousness ("talked and deteriorated") • Focal neurologic signs • Penetrating skull injury or palpable depressed skull fracture

[b]Percentages are adapted from several sources and have been rounded. Data are based on historical cohort studies and may not reflect current outcomes with aggressive surgical and critical care management.

The Glasgow Coma Scale (GCS; **Table 47.3**) is based on eye opening and the patient's best verbal and motor responses; these three individual scores should be recorded separately. The GCS is widely used as a semiquantitative clinical measure of the severity of brain injury; it also provides a guide to prognosis (**Table 47.4**). Patients who are comatose (GCS score ≤8), or who show clinical signs of herniation, require emergency interventions to reduce ICP, including 30° of head elevation, hyperventilation to a target $PaCO_2$ of 30 mm Hg, and 20% mannitol solution at a dose of 0.5 to 1.0 g/kg via rapid IV infusion (**Table 47.5**).

TABLE 47.5 Emergency Measures for Intracranial Pressure Reduction in an Unmonitored Patient With Clinical Signs of Herniation[a]

1. Elevate head of bed 15-30°.
2. Normal saline (0.9%) at 80-100 mL/h (Avoid hypotonic fluids.)
3. Intubate and hyperventilate (target P_{CO_2} = 28-32 mm Hg).
4. Mannitol 20% 1-1.5 g/kg via rapid IV infusion
5. Foley catheter
6. Neurosurgical consultation

History

The circumstances of the accident and the clinical condition of the patient before admission to the emergency room should be ascertained from records of the emergency medical services, the patient (if possible), and eyewitnesses. The force and location of head impact should be determined as precisely as possible. Specific inquiry should be made about concussion; because patients are amnesic during the concussion, only an eyewitness may accurately gauge the duration of loss of consciousness.

Patients who have "talked and deteriorated" should be assumed to have an expanding intracranial hematoma until proven otherwise. Reports of headache, nausea, vomiting, confusion, or seizure activity must be noted. A medical history, including medications and drug and alcohol use, should be obtained. Recent drug and alcohol use occurs in many trauma patients.

Radiography and Imaging

CT is the emergency imaging method of choice for head injury. CT is more informative than standard skull radiographic films for detecting skull or neck fractures and provides unsurpassed sensitivity for detecting intracranial blood. In general, all patients with a head injury should have CT, except for those who are classified as low risk (eg, without concussion; with no neurologic abnormalities on examination; and with no evidence or suspicion of a skull fracture, alcohol or drug intoxication, or other moderate-risk criteria) (see **Table 47.2**).

In GCS 13 to 15, adult patients presenting to the ED after blunt head trauma with at least one of the following—witnessed loss of consciousness, amnesia, or mental status changes—**the Canadian CT Head Rule** is a well-validated clinical support tool. This decision aide safely rules out the presence of clinically significant intracranial injuries that would require hospital admission for observation and/or neurosurgical intervention, without the need for CT imaging. Applying the Canadian CT Head Rule may allow physicians to safely reduce head CT imaging after minor blunt head trauma by approximately 30%.

Canadian CT Head Rule	
High-Risk Criteria	**Medium-Risk Criteria**
Glasgow Coma Scale <15 at 2 h postinjury	Retrograde amnesia to the event ≥30 min
Suspected open or depressed skull fracture	"Dangerous" mechanism? (pedestrian struck by motor vehicle, occupant ejected from motor vehicle, or fall from >3 ft or >5 stairs)
Any sign of basilar skull fracture?	
≥2 episodes of vomiting	
Age ≥65 y	

Alternatively, in GCS 15 (neurologically normal) adult trauma patients with witnessed loss of consciousness, the **New Orleans Head CT Rule** can help determine which blunt head trauma patients can be discharged home from the ED without undergoing a CT head or admission for further clinical observation.

New Orleans/Charity Head Trauma/Injury Rule
Headache
Emesis
Age >60 years
Drug or alcohol intoxication
Convulsion
Trauma visible above the clavicles
Short-term memory deficits

Use mnemonic "Head CTs" to remember the seven criteria. Absence of all seven criteria suggests that it is safe to discharge the patient without as head CT scan.

CT images of the head should be assessed for evidence of the presence of epidural or subdural hematoma, subarachnoid or intraventricular blood, parenchymal contusions and hemorrhages, cerebral edema, and gliding contusions related to DAI. With bone window settings, fractures, sinus opacification, and pneumocephalus may be identified.

Axial CT images of the entire cervical spine should also be obtained in all patients. If traumatic arterial dissection is possible, CT angiography of the head and neck is indicated

MRI is better for detecting subtle injury to the brain, particularly for focal (noncontusional) hemorrhagic lesions related to DAI and traumatic axonal injury (TAI) but is generally not used for emergency evaluations unless it is rapidly and readily available. Recovery of functional independence is possible in patients with brainstem TAI; however, its radiologic classification is typically performed using the histopathologic model proposed by JH Adams, in which all brainstem lesions are grouped into a single prognostic category of "grade 3 DAI." This classification system fails to consider the prognostic importance of lesions in specific brainstem regions, such as dorsal pons and dorsal midbrain, which contain arousal (ie, wakefulness) nuclei that are critical to recovery of consciousness (see Fig 47.2).

Secondary Neurologic Evaluation

On arrival at the intensive care unit (ICU), more detailed physical and neurologic examinations should be performed (the "secondary survey"). The patient should again be examined for external signs of trauma to the neck, chest, back, abdomen, and limbs. A bloody discharge from the nose or ear may indicate leakage of CSF; bloody CSF may be differentiated from blood by a positive halo test (ie, a halo of CSF forms around the blood when dropped on a white cloth sheet). If there is no admixture of blood, CSF may be distinguished from nasal secretions because the CSF glucose concentration is 30 mg/dL or more, whereas lacrimal secretions and nasal mucus usually contain less than 5 mg/dL glucose.

After determining the patient's level of consciousness (eg, alert, lethargic, stuporous, or comatose), a focused mental status examination should be performed if the patient is conversant. Particular attention should be paid to attention capabilities, concentration (eg, counting backward from 20 to 1 or reciting the months in reverse), orientation, and memory, including assessment for retrograde and anterograde amnesia.

Eye movements, pupillary size and shape, and reactivity to light should be noted. A sluggishly reactive or dilated pupil suggests transtentorial herniation with compression of the third cranial nerve. A midposition, poorly reactive, and irregular pupil may result from injury to the oculomotor nucleus in the midbrain tegmentum. Nystagmus often follows a concussion. In comatose patients, the oculocephalic and oculovestibular reflexes should be tested (see Chapter 19).

Motor examination should focus on identifying asymmetric weakness or posturing. Spontaneous movements should be assessed for preferential use of the limbs on one side. If the patient is not fully cooperative, lateralized weakness may be detected by assessment of an asymmetry in tone or tendon reflexes or by the presence of an arm drift, preferential localizing response to sternal rub, or extensor plantar reflex. Noxious stimuli, such as pinching the medial arm or applying nail bed pressure, may reveal subtle motor posturing in a limb that otherwise moves purposefully. *Decorticate posturing* (ie, flexion of arms, extension of legs) results from injury to the corticospinal pathways at the level of the diencephalon or upper midbrain. *Decerebrate posturing* (ie, extension of legs and arms) implies injury to the motor pathways at the level of the lower midbrain, pons, or medulla.

Gait is particularly important to check in low-risk patients who are treated and scheduled for release without CT. Balance and equilibrium, tested by tandem heel-to-toe walking, are frequently impaired after a concussion.

MANAGEMENT

Admission to the Hospital

Low-risk Group

Low-risk patients who meet all criteria described in **Table 47.2**, generally, may be discharged from the emergency room without CT, so long as a responsible person is available to observe the patient for the next 24 hours. In general, these are patients who did not sustain a concussion and have normal findings on neurologic examination. Patients are given a checklist of symptoms (eg, headache, vomiting, confusion) and instructed to return immediately to the emergency room if any occur.

Moderate-risk Group

Among patients who have had a concussion, a normal GCS score of 15 (eg, alert, fully oriented, and following commands) and

TABLE 47.6 Criteria for Hospital Admission After Head Injury

• Intracranial blood or fracture identified on head CT
• Confusion, agitation, or depressed level of consciousness
• Focal neurologic signs or symptoms
• Posttraumatic seizure
• Alcohol or drug intoxication
• Significant comorbid medical illness
• Lack of a reliable home environment for observation

Abbreviation: CT, computed tomography.

normal CT eliminate the need for hospital admission. These patients may be discharged to home for observation with a warning card, even in the presence of headache, nausea, vomiting, dizziness, or retrograde amnesia, because the risk of a significant intracranial lesion developing thereafter is minimal. Criteria for hospital admission for patients with head injury are listed in **Table 47.6**.

Patients with mild to moderate neurologic deficits (generally corresponding to GCS scores of 9-14) and CT findings that do not require neurosurgical intervention should be admitted to an intermediate care unit or ICU for observation. Follow-up CT at 24 hours is often helpful to check for progression of bleeding.

High-risk Group

All patients with a serious head injury are admitted to the hospital. An early neurosurgical consultation is crucial because once the patient has been stabilized, assessed, and imaged, the immediate consideration is whether emergency surgery is indicated. If the decision is made to operate, surgery should proceed immediately because delays only increase the likelihood of further brain damage during the waiting period. Medical management of severe-injury patients should take place in an ICU. Although little may be done about the brain damage that occurs on impact, ICU care may play a major role in reducing secondary brain injury that develops over hours or days.

Surgical Intervention

Simple wounds of the scalp should be thoroughly cleaned and sutured. Compound fractures of the skull should be completely debrided. Operative treatment of compound fractures should be performed as soon as possible but may be delayed for 24 hours until the patient is transported to a hospital equipped for this purpose or until the patient is hemodynamically stable. Elevation of small, depressed fractures need not be performed immediately, but the depressed fragments should be elevated before the patient is discharged from the hospital, particularly if the inner table of the skull is involved.

The treatment of massive acute subdural, epidural, or parenchymal hematomas with mass effect is *craniotomy* and surgical removal of the clot. Results from a large randomized clinical trial indicate that decompressive *craniectomy*—removal of a large unilateral or bifrontal portion of the skull—is not indicated emergently LEVEL I.[1,2] The bleeding point should be identified and either ligated or clipped. The operative results depend to a great extent on the degree of associated brain damage. In the absence of coexisting brain injury, remarkable improvement may occur after evacuation of a subdural or epidural hematoma, with disappearance of the hemiplegia or other focal neurologic signs.

Burr-hole or *twist-drill* evacuation is insufficient for acute, large, subdural, and epidural hematomas, but for liquefied, chronic, subdural hematomas, it is associated with better outcomes than craniotomy. A plastic catheter (eg, Jackson-Pratt drain) is usually placed in the subdural space for several days until the drainage subsides.

Intracranial Pressure Management

As a general rule, an ICP monitor should be placed in all head-injured patients who are comatose (ie, GCS score of 8) after resuscitation. Intracranial hypertension occurs in more than 50% of comatose patients with CT evidence of mass effect from intracranial hemorrhage or cerebral edema and in 10% to 15% of patients with normal imaging. A ventricular catheter or fiberoptic parenchymal monitor may be used. Ventriculostomy has the advantage of allowing CSF drainage to reduce ICP but has a high risk of infection (approximately 12%). The risk of infection or hemorrhage is substantially lower with parenchymal ICP monitors (approximately 1%-2%).

Normal ICP is less than 15 mm Hg, or 20 cm water. Cerebral perfusion pressure (CPP) is routinely monitored in conjunction with ICP because it is an important determinant of cerebral blood flow; CPP is defined as mean arterial BP minus ICP. The goal of ICP management after head injury is to maintain ICP less than 20 mm Hg and CPP greater than 60 mm Hg. The magnitude and duration of derangements beyond these targets is highly correlated with poor outcome after severe TBI.

Treatment of elevated ICP is most successful when a preestablished protocol is used. Treatment of elevated ICP is most successful when a preestablished protocol is used. The Seattle International Severe Traumatic Brain Injury Consensus Conference (SIBICC) stepwise management protocol for treating ICP elevations in monitored ICU patients is shown in **Figure 47.10**.

An acute, severe increase in ICP always prompts a repeat CT to assess the need for a definitive neurosurgical procedure. If the patient is agitated or appears to be fighting the ventilator, a short-acting IV sedative agent, such as propofol, or analgesic, such as fentanyl, should be given alone or in combination to attain a quiet, motionless state. Thereafter, if CPP is less than 60 mm Hg, vasopressors may lead to reduction of ICP by decreasing cerebral vasodilation that occurs in response to inadequate perfusion. Alternately, if CPP exceeds 120 mm Hg, BP reduction with IV labetalol or nicardipine may sometimes lead to a parallel decrease of ICP. The relationship between extremes of CPP and ICP in states of reduced intracranial compliance is shown in **Figure 47.11**.

Mannitol and hypertonic saline are used only after all surgical options have been exhausted and sedation and CPP optimization fail to normalize ICP. Mannitol, an osmotic diuretic, lowers ICP via its cerebral dehydrating effects. The initial dose of mannitol 20% solution is 0.5 to 1.0 g/kg, followed by doses of 0.25 to 1.0 g/kg as needed. Further doses should be given individually based on ICP measurements rather than on a standing basis. Mannitol boluses may also be used to reverse acute herniation syndromes (ie, a blown pupil) resulting from compartmental mass effect and ICP gradients. The effect of mannitol is maximal when given rapidly; ICP reduction occurs within 10 to 20 minutes and may last for 2 to 6 hours. Serum osmolality should be monitored closely and the osmolar gap calculated by subtracting the measured osmolality from the calculated osmolality. Should the osmolar gap

Tier Zero (Basic Severe TBI Care - Not ICP Dependent)

Expected Interventions:

- Admission to ICU
- Endotracheal intubation and mechanical ventilation
- Serial evaluations of neurologic status and pupillary reactivity
- Elevate HOB 30°C-45°C
- Analgesia to manage signs of pain (not ICP directed)
- Sedation to prevent agitation, ventilator asynchrony, etc. (not ICP directed)
- Temperature management to prevent fever
  - *Measure core temperature*
  - *Treat core temperature above 38°C*
- Consider antiseizure medications for 1 wk only (in the absence of an indication to continue)
- Maintain CPP initially ≥60 mm Hg
- Maintain Hb >7 g/dL
- Avoid hyponatremia
- Optimize venous return from head (eg, keeping head midline, ensure cervical collars are not too tight)
- Arterial line continuous blood pressure monitoring
- Maintain SpO_2 ≥94%

Recommended Interventions:

- Insertion of a central line
- End-tidal CO_2 monitoring

Tier 1

- Maintain CPP 60-70 mm Hg
- Increase analgesia to lower ICP
- Increase sedation to lower ICP
- Maintain $Paco_2$ at low end of normal (35-38 mm Hg/4.7-5.1 kPA)
- Mannitol by intermittent bolus *(0.25-1.0 g/kg)*
- Hypertonic saline by intermittent bolus[a]
- CSF drainage if EVD *in situ*
- Consider placement of EVD to drain CSF if parenchymal probe used initially
- Consider anti-seizure prophylaxis for 1 week only (unless indication to continue)
- Consider EEG monitoring

Principles for Using Tiers:

- When possible, use lowest tier treatment
- There is no rank order within a tier
- It is not necessary to use all modalities in a lower tier before moving to the next tier
- If considered advantageous, tier can be skipped when advancing treatment

Tier 2

- Mild hypocapnia range (32-35 mm Hg/4.3-4.6 kPa)
- Neuromuscular paralysis in adequately sedated patients if efficacious[b]
- **Perform MAP Challenge to assess cerebral autoregulation and guide MAP and CPP goals in individual patients[c]**
  - *Should be performed under direct supervision of a physician who can assess response and ensure safety*
  - *No other therapeutic adjustments (ie, sedation) should be performed during the MAP Challenge*
  - *Initiate or titrate a vasopressor or inotrope to increase MAP by 10 mm Hg for not more than 20 minutes*
  - *Monitor and record key parameters (MAP, CPP, ICP, and $PbtO_2$) before during and after the challenge*
  - *Adjust vasopressor/inotrope dose based on study findings*
- Raise CPP with fluid boluses, vasopressors and/or inotropes to lower ICP when autoregulation is intact

- Reexamine the patient and consider repeat CT to reevaluate intracranial pathology
- Reconsider surgical options for potentially surgical lessions
- Consider extracranial causes of ICP elevation
- Review that basic physiologic parameters are in desired range (eg, CPP, blood gas values)
- Consider consultation with higher level of care if applicable for your health care system

Tier 3

- Pentobarbital or thiopentone coma titrated to ICP control if efficacious[d]
- Secondary decompressive craniectomy
- Mild hypothermia (35°C-36°C) using active cooling measures

FIGURE 47.10 Interventions fundamental to the intensive care of severe traumatic brain injury patients. [a]We recommend using sodium and osmolality limits of 155 and 320 mEq/L, respectively, as administration limits for both mannitol and hypertonic saline. [b]We recommend a trial dose of neuromuscular paralysis and only proceeding to a continuous infusion when efficacy is demonstrated. [c]Rosenthal G, Sanchez-Mejia RO, Phan N, Hemphill JC III, Martin C, Manley GT. Incorporating a parenchymal thermal diffusion cerebral blood flow probe in bedside assessment of cerebral autoregulation and vasoreactivity in patients with severe traumatic brain injury. *J Neurosurg*. 2011;114:62-70. [d]Barbiturate administration should only be continued when a beneficial effect on intracranial pressure (ICP) is demonstrated. Abbreviations: CO_2, carbon dioxide; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EVD, external ventricular drain; Hb, hemoglobin; HOB, head of bed; ICU, intensive care unit; MAP, mean arterial pressure; $PbtO_2$, continuous brain tissue oxygen; SpO_2, oxygen saturation. (Adapted from SIBIC Severe TBI Guidelines.)

FIGURE 47.11 Relationship between extremes of cerebral perfusion pressure (CPP) and increased intracranial pressure (ICP) in states of reduced intracranial compliance. In the vasodilatory cascade zone, CPP insufficiency and intact pressure autoregulation leads to reflex cerebral vasodilation and increased ICP; the treatment is to raise CPP. In the autoregulation breakthrough zone, pressure and volume overload, which overwhelms the brain's capacity to autoregulate, leads to increased cerebral blood volume and ICP; the treatment is to lower CPP. (Adapted from Rose JA, Mayer SA. Optimizing blood pressure in neurological emergencies. *Neurocrit Care*. 2004;1:287-299, with permission.)

increase to greater than 15 mOsm/L, then there is a greater likelihood of mannitol leading to renal failure. Urinary losses should be compensated for with IV normal saline to avoid secondary hypovolemia. Assessment of intravascular volume status with a combination of invasive monitoring and ultrasound is generally recommended. More recently, hypertonic saline in the form of a 3% sodium chloride/acetate continuous infusion, or 10% or 23.4% sodium chloride as an alternative to mannitol bolus therapy, has been advocated for the treatment of intracranial hypertension and herniation syndromes. Studies evaluating equiosmolar doses of mannitol and hypertonic saline indicate that in most cases, hypertonic saline is at least equivalent, if not superior, to mannitol for lowering ICP in terms of the rapidity, extent, and duration of ICP reduction. The exception is in the prehospital setting where empiric administration with hypertonic saline failed to improve outcomes after TBI LEVEL 1.[3] As a general rule in the critical care setting, hypertonic saline is generally preferred in patients who are hypotensive or hypovolemic, whereas mannitol is preferable for patients who are volume overloaded or who have congestive heart failure.

Hyperventilation lowers ICP by inducing cerebral alkalosis and reflex vasoconstriction, with a concomitant reduction of CBV. Hyperventilation to P_{CO_2} levels of 28 to 32 mm Hg may lower ICP within minutes, although the effect gradually diminishes over as little as 1 to 3 hours, as acid-base buffering mechanisms correct the alkalosis within the CNS. Additionally, prophylactic hyperventilation has been shown to lead to detrimental outcomes LEVEL 1,[4] and overly aggressive hyperventilation to P_{CO_2} levels less than 26 mm Hg may potentially exacerbate cerebral ischemia and, in general, should be avoided unless jugular venous oxygen saturation or brain tissue oxygen monitoring is available to ensure that cerebral hypoxia does not occur.

High-dose barbiturate therapy with pentobarbital given in doses equivalent to those used for general anesthesia (5-20 mg/kg as a loading dose, followed by 1-4 mg/kg/h) effectively lowers ICP in most patients who are refractory to the steps outlined earlier. It can be dosed as either a continuous infusion or given as bolus injection as needed for ICP control (50-200 mg every 15 min). The effect of pentobarbital is multifactorial but most likely stems from a coupled reduction in cerebral metabolism, blood flow, and blood volume. Pentobarbital may cause profound hypotension and usually requires the use of vasopressors to maintain CPP of at least 60 mm Hg. The other major side effect of pentobarbital is prolonged immobilization and ventilator dependence, which increases the risk of nosocomial infection and exposure to other iatrogenic complications. In a clinical trial, the prophylactic use of pentobarbital was associated with poor outcome, and its use currently is reserved for cases of refractory raised ICP LEVEL 1.[5]

Mild to moderate systemic hypothermia (33°C) has been shown to reduce ICP in patients with refractory intracranial hypertension. The application of hypothermia is complex and requires a management protocol that emphasizes the use of agents such as meperidine, fentanyl, or dexmedetomidine and neuromuscular blocking agents, if necessary, to prevent shivering that increases cerebral and metabolic stress and fights the cooling process. The routine application of mild to moderate hypothermia within 8 hours of TBI, as a form of neuroprotection, or as an early-stage ICP therapy was tested in several large clinical trials and was shown not to be of benefit LEVEL 1.[6-9] For this reason, its use should be limited to the management of refractory intracranial hypertension.

Intensive Care Unit Management of Severe Head Injury

Patients with severe head injuries are best treated in an ICU (see Fig 47.10). In some hospitals, patients with head injuries are treated in a special neurologic or neurosurgical ICU. A time-coded flow sheet is helpful to allow for meticulous, continuous updating of the patient's clinical, neurologic, and physiologic status that supports crisp management decisions balancing both the increasing risk of treatment-related complications as well as potential benefits of escalation from one tier to the next (Fig 47.12).

Serial Neurologic Evaluation

The patient should be examined repeatedly to evaluate level of consciousness and the presence or absence of signs of injury to the brain or cranial nerves. Variations in level of consciousness, reflected by changes in the GCS score or the appearance of hemiplegia or other focal neurologic signs, should prompt repeat CT.

Airway and Ventilation

In general, patients who are unable to protect their airways because of depressed levels of consciousness should be intubated with an endotracheal tube. Routine hyperventilation is not recommended; in the absence of increased ICP, ventilatory parameters should be set to maintain P_{CO_2} at 30 to 40 mm Hg and P_{O_2} at 90 to 100 mm Hg.

Blood Pressure Management

If the patient shows signs of hemodynamic instability, a radial artery catheter should be placed to monitor BP. Because cerebral blood flow autoregulation is frequently impaired in acute head injury, mean BP (or CPP if ICP is being monitored) must be carefully regulated to avoid hypotension that may lead to cerebral ischemia or hypertension that may exacerbate cerebral edema. Continuous infusion, short-acting vasopressors (eg, phenylephrine and norepinephrine), and antihypertensive agents (eg, labetalol and nicardipine) are preferable because of their abilities to stabilize BP within a narrow therapeutic range. Sodium nitroprusside should be avoided because it may dilate cerebral vessels and raise ICP.

Fluid Management

Only isotonic fluids, such as 0.9% (ie, normal) saline or plasmalyte solution, should be administered to head-injured patients because the extra free water in half-normal saline or 5% dextrose in water may exacerbate cerebral edema. Hypertonic saline (ie, 3% sodium chloride/acetate solution) with a target osmolality of 300 to 320 mOsm/L may be used as an alternative in patients with significant brain edema and may reduce the number of ICP elevations, at the risk of causing fluid overload and pulmonary edema if volume status and oxygenation are not carefully monitored. Central venous pressure monitoring is helpful to guide fluid management in hypotensive or hypovolemic patients. Negative fluid balance is associated with poor outcome after TBI and should be avoided.

Nutrition

Severe head injury leads to a generalized hypermetabolic and catabolic response, with caloric requirements that are 50% to 100% higher than normal. Enteral feedings via a nasogastric or nasoduodenal tube should be instituted as soon as possible (eg, usually after 24-48 h). Early enteral feeding on day 1 after injury is generally well tolerated and has been shown to improve outcome compared

FIGURE 47.12 Tiered treatment of intracranial hypertension in adult traumatic brain injury. Clinicians must always consider both the increasing risk of treatment-related complications with as well as potential benefits of escalation from one tier to the next. Tier-3 treatments are associated with the most severe complications. Abbreviations: AKI, acute kidney injury; ALI, ; CA, cerebral autoregulation; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; EVD, external ventricular drain; ICP, intracranial pressure; MAP, mean arterial pressure; MV, mechanical ventilation; PRIS, propofol infusion syndrome; VAP, ventilator-associated pneumonia. (Adapted from SIBIC Severe TBI Guidelines and Smith M, Maas AIR. An algorithm for patients with intracranial pressure monitoring: filling the gap between evidence and practice. *Intensive Care Med.* 2019;45:1819-1821.)

with delayed feeding. Parenteral nutrition carries significant risks, primarily those of infection and electrolyte derangements, and should be used only if enteral feeding may not be tolerated.

Analgosedation

Patients may be agitated or delirious, which may lead to self-injury, forcible removal of monitoring devices, systemic and cerebral hypermetabolism, and increased ICP. Intubated patients may be sedated using a continuous IV infusion of a rapid-acting sedative agent, such as propofol, fentanyl, or remifentanil, that may be turned off periodically to allow neurologic assessments. Pain control should always be the first consideration when using analgosedation. Daily interruption of sedation in mechanically intubated patients allows for improved sensitivity to changes in neurologic status, more appropriate titration of sedation, and reduced duration of mechanical ventilation. Nonintubated patients with delirium may be treated with haloperidol 2 to 10 mg every 4 hours as needed, quetiapine 25 to 50 mg orally every 6 to 8 hours, or a similar agent.

Temperature Management

Fever (>38.3°C) is common after TBI and may be the result of infection or of central fever. Even small temperature elevations may exacerbate TBI and ischemic brain injury and should be aggressively treated. Newer cooling devices using adhesive cooling pads or intravascular heat-exchange catheters are superior to standard water-circulating cooling blankets for maintaining normothermia in comatose brain-injured patients.

Anticonvulsants

Phenytoin or fosphenytoin (15-20 mg/kg loading dose, then 300 mg/d) reduced the frequency of early (ie, first week) post-traumatic seizures from 14% to 4% in a clinical trial of patients with intracranial hemorrhage but did not prevent later seizures LEVEL 1.[10] IV valproic acid or levetiracetam is an acceptable alternative for patients with phenytoin allergy. If the patient has not had a seizure, prophylactic anticonvulsants should be discontinued after 7 days. Anticonvulsant serum levels of head-injured patients should be monitored closely because subtherapeutic levels frequently result from drug hypermetabolism, particularly in younger men. Nonconvulsive seizures and status epilepticus, which are diagnosable only with continuous electroencephalogram monitoring, occur in over 10% to 20% of comatose TBI patients, are associated with poor outcome and generally warrant aggressive treatment with continuous infusion midazolam or similar agents.

Intensive Insulin Therapy

Continuous insulin infusion therapy to control blood glucose to between 100 and 180 mg/dL in hyperglycemic patients reduces mortality in critically ill surgical patients and is increasingly being adopted as a practice option in the ICU management of severe TBI. Meticulous attention, including hourly blood glucose monitoring, must be paid to avoid excessive hypoglycemia with continuous insulin infusion.

Steroids

Glucocorticoids have been used to treat cerebral edema for years but have not been shown to favorably alter outcomes or lower ICP in head-injured patients. A large randomized controlled trial demonstrated an increased rate of death in patients given high-dose steroids during the first week after TBI LEVEL 1.[11] This was probably attributable to increased risk of infection, hyperglycemia, or other complications. For these reasons, dexamethasone and other steroids are absolutely contraindicated for use in patients with head injury.

Deep Vein Thrombosis Prophylaxis

Patients with head injury who are immobilized are at high risk for deep vein thrombosis in the legs and pulmonary thromboembolism. Pneumatic compression boots should be used routinely to protect against this risk, and patients should also be given subcutaneous heparin 5,000 units every 8 hours or enoxaparin 40 mg daily. Low-dose anticoagulants to prevent thromboembolic disease can safely be added within 48 hours after injury, even in the presence of intracranial hemorrhage, so long as hematoma expansion is not noted on serial imaging.

Gastric Stress Ulcer Prophylaxis

Patients on mechanical ventilation or with coagulopathy are at increased risk for gastric stress ulceration and should receive pantoprazole 40 mg daily IV, famotidine 20 mg IV every 12 hours, or sucralfate 1 g orally every 6 hours.

Antibiotics

The routine use of prophylactic antibiotics in patients with open skull injuries is controversial, and opinions are sharply divided. Prophylactic antibiotics with gram-positive activity, such as oxacillin, are often used to reduce the risk of meningitis in patients with CSF otorrhea, rhinorrhea, or intracranial air; however, these agents may increase the risk of infection with more virulent or resistant organisms. A single dose of an antibiotic with activity against gram-positive bacteria such as oxacillin or cefazolin should be administered immediately prior to the insertion of an intracranial monitor.

ACUTE COMPLICATIONS OF HEAD INJURY

Cerebrospinal Fluid Fistula

CSF fistulas result from tearing of the dura and arachnoid membranes. They occur in 3% of patients with closed head injury and in 5% to 10% of those with basilar skull fractures. They are usually associated with fractures of the ethmoid, sphenoid, or orbital plate of the frontal bone.

CT may demonstrate pneumocephalus (air in the subarachnoid space). Clinical manifestations include obvious leakage of CSF from a scalp laceration, the nose, or the ear. CSF leakage ceases after head elevation alone for a few days in 85% of cases. If it persists, the insertion of a lumbar drain may lower CSF pressure, reduce flow through the fistula, and hasten spontaneous closure of the dural tear. Patients with dural leaks are at increased risk for meningitis, and although the use of prophylactic antibiotics is controversial, most physicians use them. Persistent CSF otorrhea or rhinorrhea for more than 2 weeks calls for surgical repair, as does recurrent meningitis. If there is a leak and the site of the fracture is not evident, a metrizamide CT study is the diagnostic method of choice.

Carotid-Cavernous Fistula

Carotid-cavernous fistulae are characterized by the clinical triad of pulsating exophthalmos, ocular chemosis, and orbital bruit. They

result from traumatic laceration of the internal carotid artery as it passes through the cavernous sinus; approximately 20% of cases are nontraumatic, and most of these are related to spontaneous rupture of an intracavernous internal carotid artery aneurysm. Other symptoms may include distended orbital and periorbital veins and paralysis of the cranial nerves (eg, III, IV, V, and VI) that pass through or within the wall of the cavernous sinus.

Traumatic carotid-cavernous fistulae may develop immediately or within days after injury. Angiography is required to confirm the diagnosis (see Fig. 47.9). Endovascular treatment, with a balloon placed through the defect in the arterial wall into the venous side of the fistula, is the most effective means of repair and may prevent permanent visual loss caused by venous retinal infarction if performed as soon as possible after injury.

Traumatic Arterial Dissection and Vascular Injuries

Traumatic injuries may be associated with dissections of the extracranial or intracranial internal carotid or vertebral arteries, which may lead to thrombosis at the site of the intimal flap and stroke resulting from distal thromboembolism. The gold standard for diagnosis is conventional angiography, but CT and magnetic resonance angiography are often used to screen for arterial dissections. Anticoagulation with unfractionated heparin is the primary strategy to prevent intravascular thrombosis and thromboembolism. However, anticoagulation poses risks when there is evident intracranial hemorrhage or coexisting intracranial dissection with pseudoaneurysm formation. Treatment decisions must be individualized.

Basilar skull fractures are sometimes associated with thrombosis of adjacent dural sinuses; the sphenoid and transverse sinuses are most commonly involved. Symptoms are related to increased ICP or associated venous infarction. The diagnosis is established by angiography or magnetic resonance venography, and anticoagulation is the treatment of choice (see Chapter 44).

In patients with large epidural or subdural hematomas and subfalcine herniation, secondary cerebral infarction may sometimes result from compression of the ipsilateral anterior cerebral artery against the falx or posterior cerebral artery against the tentorium. Urgent neurosurgical decompression to prevent these infarcts is the only effective management strategy.

Cranial Nerve Injury

Injury to the cranial nerves can occur with basilar skull fractures (see Chapter 49). The facial nerve is the most commonly injured nerve in these cases, complicating 0.3% to 5% of all head injuries. Occasionally, the paralysis may not develop until several days after the injury. Partial or complete recovery of function is the rule with traumatic injuries to the cranial nerves, with the exception of injury to the first or second cranial nerve.

Infections

Infections within the intracranial cavity after head injury may be extradural (eg, osteomyelitis), subdural (eg, empyema), subarachnoid (eg, meningitis), or intracerebral (eg, abscess). These infections usually develop in the first few weeks after injury but may be delayed. Diagnosis is suggested by CT or MRI and confirmed by culture of the infected tissue. Treatment includes surgical debridement and administration of antibiotics.

Meningitis may follow any type of open fracture associated with tearing of the dura, including compound skull fractures, penetrating missile injury, or linear fractures that extend into the nasal sinuses or the middle ear. Meningitis occurs in as few as 2% and as many as 22% of patients with basilar skull fractures. Cases of meningitis that develop within a few days after injury are almost always caused by pneumococcus or other gram-positive bacteria, but any pathogenic organism may be the cause. Diagnosis depends on the CSF findings after lumbar puncture. The principles of treatment are those recommended for meningitis in general (see Chapter 64). The presence of a persistent CSF fistula with rhinorrhea or otorrhea favors the recurrence of meningitis; as many as seven or eight attacks have been reported. Treatment in such cases may require surgical closure of the fistula.

OUTCOMES

Outcomes that may be expected after head injury are often matters of great concern, particularly in those with serious injuries. *Depth of coma*, *CT findings*, and *age* of the patient are the variables most predictive of late outcome. Other factors of prognostic importance include the absence of pupillary responses, hypotension or hypoxemia on admission, specific patterns of injury noted on admission CT scan, persistently elevated ICP, hyperthermia, and critically reduced (<10 mm Hg) brain tissue oxygen levels. Functional outcomes from severe TBI have improved markedly over the past 20 years, although mortality remains constant at approximately 30%.

Severity of coma may be quantified using the admission GCS score (see Table 47.3), which has substantial prognostic value. Historically, patients scoring 3 or 4 (deep coma) have an 85% chance of dying or remaining vegetative, whereas these outcomes occur in only 5% to 10% of patients scoring 12 or more. In general, elderly patients do very poorly. In one series of comatose patients older than 65 years of age, only 10% survived, and only 4% regained functional independence. However, many older adults with TBI respond well to aggressive management and rehabilitation, suggesting that chronologic age and TBI severity alone are inadequate prognostic markers. TBI prognostic models do not perform optimally in this population. Death may result from progression to brain death or refractory medical complications but most often is the consequence of decisions to limit life support because poor functional recovery is anticipated. It is increasingly recognized, however, that caregivers tend to underestimate capacity for recovery from severe brain injury, and some fatal outcomes may be the result of self-fulfilling prophecy. Attempts to make a firm prognosis in severe head injuries, especially in the early stages, are hazardous because the outcome depends on so many variables. Behaviors that presage later recovery (ie, ability to communicate, verbalize intelligibly, follow commands, recognize familiar stimuli, and use common objects) may not emerge within the ICU phase (Figs. 47.13 and 47.14). The 2018 disorders of consciousness (DoC) ascending arousal network practice guidelines recommend that when clinicians are discussing prognosis with caregivers of patients with DoC who are within 28 days of injury, they must avoid statements that suggest that these patients have a universally poor prognosis. Some indices, however, are valuable as prognostic indicators (see Table 47.4).

In general, the prospects of recovery from trauma-induced coma are better than recovery from coma by other causes. Fifty percent of adults and 60% of children who experience trauma-

FIGURE 47.13 A case of good recovery following cerebral herniation with Duret hemorrhage following severe traumatic brain injury. Three months postinjury, the patient had mild left upper extremity weakness, was able to stand independently, and could walk with minimal assistance. Cognition was intact and she could verbalize in short sentences. Coronal multiplanar gradient echo imaging sequence **(A)** and axial fluid-attenuated inversion recovery sequence **(B)** demonstrating blood in the pons *(arrows)*. (From Stiver SI, Gean AD, Manley GT. Survival with good outcome after cerebral herniation and Duret hemorrhage caused by traumatic brain injury. *J Neurosurg*. 2009;110(6):1242-1246.)

induced coma for 30 days will recover consciousness within 1 year compared with 15% of patients in coma from nontraumatic causes. Recovery of consciousness is operationally defined as the ability to follow verbal commands convincingly and consistently. *Unresponsive wakefulness*, rather than the former used term *persistent vegetative state*, refers to a state of eyes open coma with no external signs of consciousness. The *minimally conscious state* refers to a transitional state between coma and full consciousness. Patients exhibit the capacity to understand and obey commands and make some purposeful behaviors but otherwise demonstrate a paucity of spontaneous thought and activity. Rehabilitation inpatients with prolonged DoC after head trauma are systematically assessed using a validated neurobehavioral assessment measure, the Coma Recovery Scale-Revised, ranging from 0 to 23, with higher scores indicating a higher level of function. The Coma Recovery Scale-Revised tracks the frequency of recovery of six behaviors that represent precursors of functional independence. A linear relationship exists between the number of behaviors recovered and degree of disability (Disability Rating Scale score) at follow-up.

Cognitive impairment is by far the most common and disabling problem among survivors of head injury. During the acute phase, disorientation and agitation are particularly common.

FIGURE 47.14 Sagittal schematic views of the basilar artery and brainstem before **(left)** and after **(right)** cerebral herniation. In a normal brainstem, the basilar perforating arteries penetrate the pons in a perpendicular fashion. With downward herniation *(large arrow)*, the basilar artery remains fixed by the circle of Willis and the caudal shift of the pons results in stretching and rupture of small pontine perforating vessels, which leads to a Duret hemorrhage *(arrows)*. (From Gean AD. *Imaging of Head Trauma*. Philadelphia, PA: Raven Press; 1994:214, Fig. 10. Previously modified with permission from Wolters Kluwer.)

In addition to cognitive and motor deficits, headache, dizziness, vomiting, or vertigo may be present in the immediate posttraumatic period. These symptoms usually disappear in a few weeks but may persist for months. Common chronic cognitive problems include impaired short- and long-term memory, attention, and concentration; slowing of psychomotor speed and mental processing; and changes in personality. There may be loss of memory for the events that occurred in the immediate period after recovery of consciousness (ie, *posttraumatic amnesia*) and a similar amnesia for the events immediately preceding the injury (ie, *retraumatic amnesia*). These periods of amnesia may encompass days, weeks, or years. Depression occurs in up to 40% of TBI survivors during the first year of recovery and is highly amenable to medical therapy. With time, there is usually considerable improvement in the signs and symptoms of brain damage, but permanent sequelae are common. Even at the milder range of TBI, patients presenting to U.S. level 1 trauma centers report persistent, injury-related life difficulties at 1 year postinjury, suggesting the need for more systematic outpatient follow-up of patients with mild traumatic brain injury (mTBI) to provide treatments and reduce risk of chronic problems after mTBI.

Early cognitive, physical, and occupational therapy is an important part of optimizing recovery after TBI. Physical therapy, including range-of-motion exercises to prevent limb contractures, may begin even while patients are still in the ICU. Once the patients are stabilized, they can be transferred to an acute or subacute rehabilitation facility. Whether cognitive rehabilitative measures truly improve neuropsychological outcome remains to be established.

In a study of patients with moderate or severe injuries, only 46% returned to work 2 years later, and most of those who did return to work did not go back to their original work. Only 18% were financially independent, inducing considerable stress on the family. Vocational training may play a key role in helping patients reintegrate into the workforce.

Postconcussion Syndrome

About 40% of patients who have sustained minor or severe injuries to the head complain of dizziness, fatigue, insomnia, irritability, restlessness, and inability to concentrate. Often, there is overlap with mood disorders, including anxiety and depression, migraines, or other premorbid neuropsychiatric conditions. This group of symptoms, which may be present for only a few weeks or may persist for years, is known as *postconcussion syndrome* (see also Chapter 46).

Postconcussion syndrome is somewhat misleadingly named because affected individuals need not have suffered loss of consciousness. There are no criteria to define the role of either physiologic or psychological factors in the etiology of postconcussion syndrome. Patients may be severely disabled yet have normal findings on neurologic examination and no magnetic resonance evidence of brain injury. The correlation between the severity of the original injury and the severity and duration of later symptoms is poor. For instance, the incidence of postconcussion syndrome is not related to the duration of retrograde amnesia, coma, or posttraumatic amnesia. In some patients, symptoms may be related to the brain damage; in others, they seem to be entirely psychogenic. In practice, it is often difficult to sort out the complicated origins of this disorder.

Posttraumatic symptoms may develop in patients who had previously shown normal adjustment but are more likely to occur in patients who had psychiatric symptoms before the injury. Factors such as domestic or financial difficulties, unrewarding occupations, and the desire to obtain compensation, financial or otherwise, tend to produce and may prolong the symptoms once they have developed.

The prognosis of the postconcussion syndrome is uncertain. In general, progressive improvement may be expected. The duration of symptoms is not related to the severity of the injury. In some patients with only mild injuries, symptoms continue for long periods, whereas patients with severe injuries may have only mild or transient symptoms. By and large, however, it is a matter of 2 to 6 months before the headache and dizziness, and the more definite mental changes, show much improvement. Treatment for postconcussion syndrome is based on psychotherapy, cognitive and occupational therapy, vocational rehabilitation, and treatment with antidepressant or antianxiety agents. However, the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) study revealed that a large proportion of patients with mTBI do not receive any follow-up care during the first 3 months after injury even when they experience ongoing postconcussive symptoms or have an abnormal head CT.

Seizures and Posttraumatic Epilepsy

Posttraumatic seizures may be immediate (ie, within 24 hours), early (ie, within the first week), or late (ie, occurring after the first week).

The exact incidence of seizures after head injury is unknown, but figures in the literature vary from 2.5% to 40%. As a rule, the more severe the injury, the greater the likelihood that seizures will develop. The overall incidence of seizures is about 25% in those with brain contusion or hematoma and as high as 50% in those with penetrating head injury.

Immediate seizures are infrequent; they are risk factors for further early seizures but not for late seizures. Early seizures occur in 3% to 14% of patients with head injury who are admitted to the hospital. Risk factors include depressed skull fracture, penetrating head injury, intracranial hemorrhage (ie, epidural, subdural, or intraparenchymal), prolonged unconsciousness (ie, >24 h), coma, and immediate seizures; the risk of early seizures in patients with any of these risk factors is 20% to 30%. Children are more likely to develop early posttraumatic seizures than are adults. Patients who experience early seizures remain at risk for late seizures and should be maintained on anticonvulsants after discharge from the hospital.

The overall incidence of late seizures (eg, posttraumatic epilepsy) after closed-head injury is 5%, but the risk is as high as 30% among patients with intracranial hemorrhage or a depressed skull fracture and 50% among patients who have experienced early seizures. About 60% of patients experience their initial seizures during the first year, but the risk of seizures remains increased for up to 15 years after a severe head injury. Because 25% of patients have only a single late seizure, many practitioners begin anticonvulsants only after a second seizure occurs. Therapy of posttraumatic epilepsy is discussed further in Chapter 60.

Posttraumatic Movement Disorders

Movement disorders are rare sequelae of head injury. Action tremor is most common, although its pathogenesis remains obscure. Cerebellar ataxia, rubral tremor, and palatal myoclonus have been described in patients with focal shearing injuries of the

superior cerebellar peduncle, midbrain, and dentato-rubro-olivary triangle, respectively. Parkinsonism and other basal ganglia syndromes have been reported after a single episode of head trauma.

PEDIATRIC TRAUMA BRAIN INJURY

Injuries are the leading cause of death in children, and brain injury is the most common cause of pediatric traumatic death (see also Chapter 151, Pediatric Brain Injury and Shaken Baby Syndrome). Motor vehicle accidents account for the largest number of severe injuries in children, but children are also prone to unique forms of injury, such as birth injury and child abuse. Children are more likely than adults to experience brain swelling and seizures after head injury and, in general, make better recoveries than do adults.

The new Brain Trauma Foundation guidelines for the management of pediatric severe TBI include an algorithm for first- and second-tier therapies. These guidelines emphasize the importance of maintaining CPP between 40 and 50 mm Hg while providing treatments to keep ICP <20 mm Hg. The treatment algorithm prioritizes the avoidance of hypoxia, hypocarbia, and circulatory compromise during stabilization; does not recommend prophylactic hypothermia; recommends seizure prophylaxis and ICP monitoring; and promotes hyperosmolar therapy with hypertonic saline and CSF removal via an external ventricular drain as initial steps to treat elevated ICP. The guidelines also address brain tissue oxygenation monitoring and advanced therapies for refractory intracranial hypertension.

MISSILE-RELATED CEREBRAL BLAST INJURY

Historically, penetrating military missile and blast injuries to the brain have led to a uniformly fatal outcome. With improvements in body armor and helmet construction, however, a previously unrecognized syndrome of cerebral *blast injury* has been described in soldiers injured in the United States–Iraq conflict. The syndrome is produced by explosive devices that propel a blast wave and a shower of metallic fragments. In addition to producing concussion, DAI, and the typically encountered forms of acute intracranial bleeding, cerebral blast injury is manifest as massive brain swelling and diffuse arterial vasospasm that begins within several days and resolves on average of 2 weeks after the injury. The syndrome is attributed to diffuse high-frequency shock wave–mediated tissue injury at the time of impact. Hemicraniectomy is often used as a lifesaving procedure because standard measures to reduce brain edema and control ICP often fail despite absence of data regarding its efficacy. Arterial vasospasm, which can result in delayed cerebral infarction, can be treated successfully with balloon angioplasty.

Traumatic Spinal Cord Injury 48

Christopher E. Mandigo, Michael G. Kaiser, and Peter D. Angevine

KEY POINTS

1. About 12,000 new cases of traumatic spinal cord injury (SCI) occur annually in the United States
2. Any patient with suspected SCI should be immobilized with a hard cervical collar or a rigid head-strap with backboard until definitive imaging can take place
3. The complete absence of any sign of fracture or misalignment of the bony structures on neck CT indicates a less than 0.1% chance of the patient harboring a clinically significant unstable cervical spine injury
4. The ASIA impairment scale grades the severity of SCI from A (complete loss of motor and sensory loss below the level of injury) to E (normal).
5. Current guidelines do not recommend administration of methylpredisolone or other steroids for traumatic SCI.
6. Current guidelines recommend maintenance of mean arterial pressure at a minimum value of 85 to 90 mm Hg for the first 7 days after injury to optimize spinal cord perfusion.

INTRODUCTION

Traumatic spinal cord injury (SCI) is a sudden event with possibly catastrophic effects that may create a medical, financial, and social burden for the individual and society. Adequate management of these patients requires knowledge of SCI, including epidemiology and pathophysiology, acute and chronic medical complications, and long-term rehabilitation and social needs.

ETIOLOGY AND EPIDEMIOLOGY

Epidemiologic data can guide the use of resources for treating and preventing SCI. The best source of this information for the United States is the National Spinal Cord Injury Database, which has been collecting information from facilities that have participated in the Model Spinal Cord Injury System since 1973. This database includes data from an estimated 13% of new SCI cases each year and has information on over 25,000 people with SCI. SCI occurs in the United States in approximately 40 per 1 million people per year, which results in about 12,000 new cases annually. This figure does not include injuries that result in fatality before hospital arrival, which may double the number of injuries. Currently, 225,000 to 300,000 people are living with SCI.

SCI primarily affects young adults aged between 16 and 30 years, but the average is increasing. The average age in the 1970s was 28.7 years; in the period 2005-2008, it was 39.5 years. The median age is 27 years, and 65% of SCI patients are younger than 35 years. The highest incidence occurs between ages 20 and 24 years. The most significant changes between the 1970s and 2005-2008 have occurred at the extremes of age. The proportion of patients older than 65 years has increased from 5% to 11%, and the proportion of children from birth to 15 years has decreased from 6% to 2%. The increasing age could arise from data collection bias, improved survival of older patients in the acute period of SCI, or in age-specific incidence rates. That is, the larger population of elderly patients requires special consideration for medical, surgical, and rehabilitative care.

Seventy-eight percent of SCI patients are male. Among those injured after 2000, 63% were White, 23% were African American, 12% were Hispanic, and 2% were from other racial or ethnic groups.

Motor vehicle accidents account for approximately 40% of cases, a figure that has been increasing in developing countries due to increases in motorized transportation, poor infrastructure, and regulatory challenges. Falls account for 30% of all cases and have been increasing in developed countries due to aging of the population. Work-related injury (10%), sports (7%), and violence, typically gunshot wounds (15%), account for most of the remaining causes of SCI. Most injuries occur on the weekends and during the summer months.

Since 2000, the most frequent neurologic category at discharge is incomplete tetraplegia (34%), followed by complete paraplegia (23%), complete tetraplegia (18%), and incomplete paraplegia (19%). Less than 1% of persons experienced complete neurologic recovery by hospital discharge. The average length of hospital stay for a patient with SCI was 15 days in 2005, and the length of rehabilitation stay was 36 days. As one might expect, length of stay for patients with neurologically complete injuries is significantly longer. The life expectancy for patients with SCI is significantly less than those for uninjured people. Mortality rates are significantly higher during the first year after injury than during subsequent years. As shown in Table 48.1, adapted from the National Spinal Cord Injury Database Web site, life expectancy rates for SCI are directly related to the severity of injury.

There are profound sociologic and economic effects from SCI. About 57% of people with SCI were employed at the time of their injury. Ten years after injury, only 32% of persons with paraplegia and 24% with tetraplegia are employed. About 80% to 90% of patients with SCI are eventually discharged to a private residence, and only 6% are discharged to nursing homes. The rest are discharged to hospitals, group living situations, or other destinations. Most SCI patients (53%) are single at the time of injury, and those who are married, or become married, are slightly more likely to become divorced than uninjured individuals. The average yearly and lifetime costs of SCI patients are

TABLE 48.1 Life Expectancy After Spinal Cord Injury[a]

		For Persons Who Survive the First 24 h					For Persons Surviving at Least 1 y Postinjury				
Age at Injury (y)	No SCI	Motor Functional at Any Level	Para	Low Tetra (C5-C8)	High Tetra (C1-C4)	Ventilator Dependent at Any Level	Motor Functional at Any Level	Para	Low Tetra (C5-C8)	High Tetra (C1-C4)	Ventilator Dependent at Any Level
20	58	53	45	40	36	17	53	46	41	37	24
40	40	34	28	23	20	7	35	28	24	21	11
60	22	18	13	10	8	2	18	13	10	9	3

SCI, spinal cord injury; para, paraplehia; tetra, tetraplegia.
[a]Life expectancy in years based on age and injury severity.

directly related to the severity and level of injury. For example, a patient with high tetraplegia (injury at C1-C4) is estimated to have expenses totaling $775,000 in the first year and $140,000 for each subsequent year. A 25-year-old with a C1-C4 injury will have a lifetime expense of $3 million, and a 50-year-old will have an expense of $1.8 million. A patient with low tetraplegia (injury at C5-C8) will have expenses of $500,000 in the first year and about $55,000 for each subsequent year. Paraplegics and incomplete motor injuries cost from $225,000 to $300,000 for the first year and $15,000 to $30,000 for each subsequent year. These numbers do not reflect the additional indirect costs that relate to unemployment and loss in productivity, which average another $60,000 per year per patient.

Nontraumatic SCI affects a large number of people and can result from a number of etiologies (see Chapter 115). These include multiple sclerosis, neoplastic diseases, vascular disease, inflammatory disease, infections, and degenerative spinal stenosis. This population of patients more commonly presents with incomplete lesions and over a subacute or chronic period. The extent of injury at presentation, the response to treatment, and the prognosis of the underlying disease process will guide medical therapy and the ultimate rehabilitation goals.

MECHANISM OF INJURY

It is generally accepted that acute SCI is a two-step process that involves primary and secondary mechanisms. The primary mechanism results from the initial mechanical injury due to local deformation and energy transformation, whereas the secondary mechanisms encompass a cascade of biochemical and cellular processes that are initiated by the primary process and cause ongoing cellular damage and death.

Primary SCI is most commonly a combination of the initial impact as well as subsequent persisting compression. The most frequent primary mechanism of SCI is impact of bone and ligament against the spinal cord from high translational forces, such as that generated by flexion, extension, axial rotation, or vertebral compression. These motions may result in a variety of vertebral column injuries, which can be identified through imaging studies such as plain radiographs, computed tomography (CT) scans, or magnetic resonance imaging (MRI) scans. The spinal cord may consequently be compressed, stretched, or crushed by fracture or dislocations, burst fractures of the vertebral body, or acutely ruptured intervertebral disks. Injury can result from only the initial impact without ongoing compression. These may occur from severe ligamentous injuries in which the spinal column dislocates and then spontaneously reduces or when there is preexisting cervical spondylosis or spinal stenosis. In this circumstance, a trivial injury may cause major neurologic damage even without obvious fracture or dislocation after the event.

Similarly, SCI from sharp bone fragments or stabbing or missile injuries can produce a mixture of spinal cord laceration, concussion, contusion, and/or compression. Direct injuries, like indirect injuries, may be partial or complete in their destruction of the cord.

An understanding of the mechanism of injury and the radiographic findings can provide insight into the biomechanical stability of the vertebral column after SCI. For example, flexion injuries, particularly in the cervical and thoracic regions, may cause anterior compression fractures of vertebral bodies and unilateral or bilateral facet joint dislocation, which can cause spinal cord compression and spinal instability. Severe axial loading can cause complete fracture of the vertebral body with displacement of bony fragments and disk material into the spinal canal and SCI. Any combination of forces may occur in a single case. Understanding the mechanism of injury permits a more complete assessment of the underlying cord injury and the instability of the spinal column.

Secondary mechanisms that result from biochemical cascades that occur after the initial event are a source of ongoing SCI and neurologic deterioration. These cause damage to neural tissue on the cellular level and include the pathologic effects of microvascular changes, excitatory amino acids, cell membrane destabilization, free radicals, inflammatory mediators, and neuroglia apoptosis.

PATHOBIOLOGY

Gross Pathology

The pathology of SCI has been divided into four relatively simple groups based on gross findings: solid cord injury, contusion/cavity, laceration, and massive compression. Solid cord injury refers to a cord that grossly appears normal without evidence of softening, discoloration, or cavity formation. However, damage to the cord can be clearly seen on histologic examination. Contusion or cavity injuries have no breach or disruption in the surface anatomy, and there are no dural adhesions. Areas of hemorrhage and necrosis (eventually evolving into cysts) are readily identified in the cord parenchyma. In many instances, these lesions taper rostrally and caudally in a cone-like fashion along the ventral regions of the posterior columns. Lacerations result in clear-cut disruption of the surface anatomy. This type of injury is most often caused by penetrating missiles or sharp

fragments of bone. The lesions are characterized by a break in the glia limitans, with damage to the underlying cord parenchyma. The epicenter of the injury generally shows minimal to no evidence of cavity formation; rather, the lesion is dominated by the deposition of a variable amount of collagenous connective tissue that, in most cases, is adherent to the overlying meninges. With massive compression injury, the cord is macerated or pulpified to a varying degree. This lesion is often accompanied by severe vertebral body fractures or dislocations. In many instances, the epicenter of this lesion is replaced by connective tissue scar and fragments of nerve roots. The tissue response is similar to that seen with laceration injuries where extensive fibrous scarring occurs over time.

There are additional anatomic characteristics of SCI worth noting. The lesion may be surprisingly small and may involve no more than a single spinal cord segment. There may be multiple lesions, especially with gunshot wounds. It is also rare to observe a complete transection of the spinal cord; on close examination, there is almost always a small amount of residual tissue traversing the cord.

Histopathology

The histologic changes in SCI can be divided into immediate, acute, intermediate, and late phases.

Immediate Phase (Initial 1-2 H)

The immediate event, presumably arising from the primary injury, consists of the actual mechanical disruption of tissue that occurs at the time of injury, such as tears, compression, and distortions. Vascular changes are commonly found and are characterized by vasodilatation, congestion (hyperemia), and petechial hemorrhages. In many cases, however, no abnormalities are observed during this early time period, particularly in the absence of a massive compression or laceration injury. This lack of pathologic changes in the early period reflects the observation that the pathology of SCI is also due to secondary phenomena, which include progressive edema, ischemia, hemorrhage, inflammation, hyperthermia, as well as calcium-, free radical-, nitric oxide- and glutamate-mediated cell injury.

Acute Phase (Hours to 1-2 D)

Vascular changes, edema, hemorrhage, inflammation, and neuronal and myelin changes characterize this phase. Edema may be vasogenic or cytotoxic. Vasogenic edema is leakage of plasma fluid into the extracellular space from breakdown of the blood-brain barrier. Cytotoxic edema results from intracellular swelling after cell death. Edema from either mechanism may result in pressure-induced ischemia caused by diminished blood flow to the injured region. Edema is seen from 3 hours to 3 days after injury. In addition to creating pressure effects, cell swelling may also alter astroglial functions.

Injury to vessels may lead to hemorrhage, which occurs primarily in the gray matter following contusion injury. Hemorrhages are primarily due to rupture of postcapillary venules or sulcal arterioles, either from mechanical disruption by the trauma or from intravascular coagulation leading to venous stasis and distention.

The inflammatory response that follows early after injury is a complex process involving vascular changes, cellular responses, and chemical mediators. There is a mild influx of neutrophils within 1 day, a peak at 2 days, and most are gone by 3 days. It is likely that the neutrophilic response is neurotoxic in nature, as these cells normally act to eradicate infection through the release of free radicals.

Neurons are very vulnerable to injury following SCI. Most neurons die from necrosis, but neuronal apoptosis also has been observed. Acute injury is characterized by axonal swelling, manifested as retraction balls or spheroids. Myelin breakdown occurs early following SCI. It is characterized initially by swelling of myelin sheaths and ultimately by its fragmentation and phagocytosis by macrophages. The loss of myelin occurs with the destructive process and is almost always associated with axonal pathology. Oligodendrocytes, like neurons, are exquisitely sensitive to SCI and undergo necrosis and apoptosis. It is likely that the death of oligodendrocytes contributes significantly to the process of wallerian degeneration.

Intermediate Phase (Days to Weeks)

Over the ensuing days and weeks, there are prominent glial responses with the elimination of necrotic debris, the beginning of astroglial scarring, the resolution of edema, the revascularization of tissue, and restoration of the blood-brain barrier.

Late Phase (Weeks to Months/Years)

The later phases of SCI are characterized by wallerian degeneration, astroglial and mesenchymal scar formation, development of cysts and syrinx, and schwannosis.

Wallerian degeneration is the anterograde disintegration of axons and their myelin sheaths that have been transected following injury. It is characterized by distorted and fragmented myelin sheaths with absent or malformed axons. An astroglial "scar," which comprises tightly interwoven astrocyte processes and extracellular matrix, eventually replaces the destroyed myelinated axon. Wallerian degeneration is a protracted process and may take more than a year to complete. The spinal cord may also be replaced by fibrous connective tissue and collagen. This occurs particularly after lacerating-type injuries and is stimulated by violation of the glia limitans. This abnormal healing coupled with astroglial scarring are thought to create physical and biochemical barriers to axonal migration and spinal cord healing.

Another late finding is the formation of cysts and syrinxes, which may be single, multiple, or multiloculated. Cysts and syrinxes are surrounded by an astrogliotic wall and represent the final "healing" phase of the necrotic process. These cavities are filled with extracellular fluid and commonly contain residual macrophages, small bands of connective tissue, and blood vessels. These cavities typically do not create a clinical problem, except that they do not provide a good substrate for regeneration.

Schwannosis is an aberrant intra- and extramedullary proliferation of Schwann cells with associated axons. It is similar, if not identical, to traumatic neuromas that occur in injured peripheral nerves. Varying amounts of spinal cord tissue may be replaced by schwannosis. The Schwann cells are introduced into the spinal cord after penetrating injuries. The incidence of schwannosis in human SCI is very high and directly correlates with time after injury, suggesting an ongoing mechanism. Its clinical significance is unclear. The prolific schwannosis may be a physical barrier to spinal cord healing. The aberrant axons that are part of this process may have untoward physiologic consequences and potentially contribute to pain, spasticity, and other abnormal responses observed in the chronically injured patient with SCI.

In general, the morphologic responses in human SCI are stereotyped and follow discernible patterns. Early glial (astrocytic and microglial) responses may greatly influence the outcome of SCI.

DIAGNOSIS, NEUROLOGIC ASSESSMENT, AND CLASSIFICATION

Clinical Evaluation

The diagnosis and initial management in patients with SCI often are intertwined, as a large percentage of patients present acutely, often with multisystem trauma, and require rapid assessment and medical intervention.

Prehospital trauma protocols are critical to prevent further injury to the spinal cord, particularly by modifying factors that contribute to secondary spinal cord damage. *Any patient with suspected SCI should be immobilized with a hard cervical collar and/or a rigid head-strap/backboard until definitive neurosurgical assessment can take place.* Treatment of hypoxia and hypotension, proper monitoring of vital signs, and transfer to an appropriate trauma center will affect ultimate outcomes positively.

On arrival to the trauma center, a rapid assessment should be undertaken to assess the status of the airway, respiratory, and circulatory systems. In addition, a cursory assessment of the neurologic status ("disability") and removal of all clothing with attention to possible injuries missed on the primary survey ("exposure") are now included in the initial steps of trauma protocols. Clinical signs of shock and hypoxia require immediate attention and appropriate therapy.

Specific diagnosis of SCI requires a more comprehensive neurologic exam as outlined later in the text with the steps necessary to determine the exact spinal cord impairment. Concomitant with the physical exam, complete and accurate imaging studies of the spinal column are necessary if SCI is suspected. These can enhance the accuracy of diagnosis and determine the extent of spinal column injury, especially in a comatose, confused, or uncooperative patient. Imaging studies are not necessary when patients are awake, are alert and cooperative without evidence of intoxication, do not have evidence of neurologic injury, and have no pain or tenderness along the spine to palpation and no associated injuries distracting from the general evaluation.

Imaging Studies

Risk Stratification

Trauma patients typically arrive with neck collars. Some patients are clearly at high risk, whereas other can be cleared clinically in the emergency department or intensive care unit without imaging. The cervical collar and spinal precautions should remain in place, and cervical spine imaging is clearly necessary; when clear symptoms, neck pain, or distracting conditions exist, clinical conditions are met (Table 48.2). National Emergency X-Radiography Utilization Study criteria (Table 48.3) address the question of who does not require imaging after presenting with head or neck trauma. *A patient who meets all five National Emergency X-Radiography Utilization Study criteria is deemed to have a low probability of injury to the cervical spine and can be cleared clinically without imaging because the risk of significant injury is miniscule* LEVEL 2.[1] The Canadian C-Spine Rule offers even slightly better sensitivity and specificity for identifying low-risk patients but is a bit more complicated to use.

TABLE 48.2 High-Risk Criteria for Patients Who Clearly Need C-Spine Imaging

- Altered mental status (Glasgow Coma Scale <15)
- Neurologic deficit (ie, limb weakness or paralysis, numbness, tingling)
- Distracting injuries present
- Neck pain or tenderness present
- Decreased range of motion of the cervical spine

Cervical X-Rays

Anteroposterior (AP) and lateral x-rays can be taken of the appropriate spinal region as directed by the clinical evaluation. AP and lateral x-rays of the cervical spine, visualizing the superior part of the first thoracic vertebral body, and open-mouth, odontoid radiographic views can form part of the initial radiologic survey. However, due to its ease of use and superior sensitivity, most centers go directly to cervical spine CT as the initial imaging study of choice. When CT scanning is available, plain x-rays contribute no additional information and need not be obtained.

Upright flexion and extension films, when appropriate, are useful for assessing biomechanical instability due to ligamentous injury. In suspected thoracic and lumbar injuries, AP, lateral, oblique, upright, and dynamic (flexion/extension) views may be necessary. Indications for thoracolumbar x-rays include falls greater than 6 ft, expulsion from motor vehicles, complaints of back pain, associated injuries, and altered mental status with an unknown mechanism of injury.

Cervical Computed Tomography

High-resolution CT scanning (see Chapter 21) with sagittal and coronal reconstruction is the best procedure for evaluating uncertain findings seen on x-rays as well as for detecting bone pathology (Fig. 48.1). The study should be performed from the occiput to T1 with three-dimensional sagittal and coronal reformats. Three-dimensional reconstructions allow for visualization in the coronal, sagittal, and axial planes and provide superior injury detection compared with plain x-ray. The main limitation of CT rests in its relative inability to detect changes in soft tissues including the spinal cord and ligamentous structures.

Whether it is safe to remove a neck collar in a comatose or obtunded patient with a normal neck CT has long remained a

TABLE 48.3 National Emergency X-Radiography Utilization Study Criteria for Low-Risk Patients Who Do Not Require Imaging After Head or Neck Injury[a]

1. No tenderness at the posterior midline of the cervical spine
2. No focal neurologic deficit
3. Normal level of alertness
4. No evidence of intoxication
5. No clinically apparent, painful injury that might distract the patient from the pain of a cervical spine injury

[a]In these patients, the neck collar can be removed and the patient cleared clinically after demonstrating full range of motion with no neck pain or point tenderness.

FIGURE 48.1 Type 2 acute dens fracture (*blue arrow* and *green arrow*) on sagittal T1- **(left)** and T2-weighted **(center)** magnetic resonance imaging and a computed tomography sagittal reconstruction *(red arrow)* **(right)**. (Images courtesy of Dr. Alexander Khandji.)

vexing clinical conundrum. In the past, it was felt that it was necessary to obtain a cervical MRI within 72 hours in order to rule out possible ligamentous injury, which appears as swelling or thickening of the interspinal ligaments. More recent data indicate that in obtunded or intubated patients, the use of modern CT alone is sufficient to exclude unstable cervical spine injuries. The complete absence of any sign of fracture or misalignment of the bony structures indicates a less than 0.1% chance of the patient harboring a clinically significant unstable cervical spine injury LEVEL 3.[2]

MRI (see Chapter 22) is the best technique for imaging the spinal cord itself. Specific indications for MRI scanning include a neurologic deficit with normal x-rays, lack of correlation between a neurologic deficit and x-ray findings, deterioration following closed reduction, and failed attempts at closed reduction. Multiplanar, high-resolution MRI with T1-weighted and gradient echo or T2-weighted imaging is the most specific and sensitive technique for assessing soft-tissue paraspinal lesions, disk herniation, spinal cord hemorrhage, spinal cord edema, and intra- or extradural hemorrhage (**Fig. 48.2**). The ability to adequately monitor the critically injured must be a priority when MRI is considered. If MRI is not available or possible, CT myelography is the current best alternative.

Neurologic Assessment and Classification

The most widely accepted, standardized method of classifying SCI is the *International Standards for Neurological and Functional Classification of Spinal Cord Injury* published jointly by the American Spinal Injury Association (ASIA) and the International Medical Society of Paraplegia. It is more commonly known as the ASIA Impairment Scale. This is an excellent guide for clinical evaluation and neurologic assessment and allows uniform comparisons among clinicians and researchers.

The ASIA Impairment Scale is scored from A to E and is detailed in **Table 48.4**. The steps to classify injury severity in a patient with SCI are described in **Table 48.5**. There are some terms that require clear definitions for categorizing impairments within the ASIA scoring system. The motor level is the most caudal key muscle group that is graded 3 out of 5 or greater, with the segments cephalad to that level graded normal strength (5 out of 5). The sensory level is the most caudal dermatome to have normal light touch and pinprick sensation on both sides. The neurologic level of injury is the most caudal level at which both motor and sensory modalities are intact. A complete injury is the absence of motor and sensory function in the lowest sacral segments. An incomplete injury has preservation of motor or sensory function below the neurologic level of injury that includes the lowest sacral segments. A zone of partial preservation describes all segments below the neurologic level of injury that have preserved motor or sensory findings; this is used only in complete injuries.

A subset of SCIs has been grouped by their specific clinical features into six clinical syndromes: Brown-Séquard, central cord, anterior cord, posterior cord, conus medullaris, and cauda equina.

Brown-Séquard Syndrome

This syndrome is characterized anatomically by a hemicord injury with ipsilateral proprioceptive and motor loss and contralateral pain and temperature sensation loss below the level of the lesion. The pattern of neurologic deficits observed in Brown-Séquard injuries result from the local spinal cord anatomy. Pain and temperature fibers cross to the opposite side of the spinal cord at the level of nerve root entry, whereas the proprioception and motor fibers decussate at the level of the brainstem. Brown-Séquard accounts for 1% to 5% of all traumatic SCIs. The most common presentation is the Brown-Séquard plus syndrome, which refers to

FIGURE 48.2 Left: Non–fat-saturated T2 image showing anterior subluxation of C7 on T1 (with anterior teardrop fracture of T1 *blue arrow*) and widened interspinous space C7-T1 posteriorly *(green arrow)*. **Right:** Sagittal computed tomography reconstruction demonstrating anterior teardrop fracture of T1 *(red arrow)*. (Images courtesy of Dr. Alexander Khandji.)

a relative ipsilateral hemiplegia with a relative contralateral hemianalgesia. Although Brown-Séquard traditionally has been associated with stab or missile injuries, a variety of etiologies may cause this syndrome. Brown-Séquard has the best prognosis for ambulation of the SCI clinical syndromes, as 75% to 90% of patients ambulate independently in long-term follow-up.

Central Cord Syndrome

This lesion is characterized by disproportionately more motor impairment of the upper than the lower extremities, bladder dysfunction, and varying degrees of sensory loss below the level of the lesion. The most common presentation occurs in older patients with preexisting cervical spondylosis who experience hyperextension injuries of the cervical spine. Cord compression occurs between osteophyte-disk complexes anteriorly and infolded ligamenta flava posteriorly. Studies have reported falls as the most common etiology, followed by motor vehicle accidents. Recent evidence from clinical pathologic studies using MRI scans has demonstrated that this clinical pattern likely results from injury to the corticospinal tract in the cervical spine, which affects

TABLE 48.4 American Spinal Injury Association Impairment Scale

A	Complete	No sensory or motor function preserved in the lowest sacral segments (S4/S5)
B	Sensory incomplete	Sensory but no motor function preserved below the neurologic level, including the sacral segments
C	Motor incomplete	Motor function is preserved below the neurologic level, and more than half of the key muscles below the level have a grade <3, and there is some sacral sensory and/or motor sparing.
D	Motor incomplete	Motor function is preserved below the neurologic level, and more than half of the key muscles below the level have a grade ≥3, and there is some sacral sensory and/or motor sparing.
E	Normal	Sensory and motor functions are normal. There can be reflex abnormalities.

TABLE 48.5 Physical Examination Steps for Classifying Spinal Cord Injury

1. Perform sensory examination in 28 dermatomes bilaterally for pinprick and light touch, including the S4/S5 dermatome, and test for anal sensation.
2. Determine sensory level (right and left).
3. Perform motor examination in the 10 key muscle groups, including anal contraction.
4. Determine motor level (right and left).
5. Determine neurologic level of injury.
6. Classify injury as complete or incomplete.
7. Categorize ASIA Impairment Scale (A-E).
8. Determine zone of partial preservation if ASIA A.

Abbreviation: ASIA, American Spinal Injury Association.

the distal, more than proximal, limb musculature and not the specific somatotopic representation within the corticospinal tract. It is considered the most common of the SCI syndromes, accounting for approximately 9% of all traumatic SCIs. Central cord syndrome generally has a favorable prognosis for functional recovery, especially in younger patients with good hand function, evidence of early motor recovery, and absence of lower extremity impairment.

Anterior Cord Syndrome

This syndrome results from a lesion that affects the anterior two-thirds of the spinal cord with preservation of the posterior columns. It is characterized by complete paralysis and loss of pain and temperature sensation below the level of the lesion, accompanied by preservation of touch and proprioception. It occurs in 3% of all traumatic SCIs. It can result from flexion injuries, direct damage from bony fragments or disk compression, or secondary to occlusion of the anterior spinal artery. This syndrome carries a poor prognosis for functional improvement.

Posterior Cord Syndrome

This is the least common of the clinical syndromes and has an incidence of less than 1%. It is a lesion of the posterior columns with resultant loss of touch and proprioception below the level of injury and preservation of pain and temperature sensation and motor strength. It can be caused by hyperextension, posterior spinal artery occlusion, or nontraumatic etiologies such as tumors or vitamin B_{12} deficiency.

Conus Medullaris and Cauda Equina Syndromes

Conus medullaris syndrome is an injury of the caudal spinal cord (conus) and its associated sacral nerve roots within the spinal canal. The conus typically sits at the level between the first and second lumbar vertebrae. This condition is characterized by a combination of upper and lower motor neuron signs. Findings include saddle anesthesia, areflexic bladder and bowel, and variable degrees of lower extremity weakness and sensory loss.

Cauda equina syndrome results from an injury to the lumbosacral nerve roots within the neural canal below the conus medullaris and presents with saddle anesthesia, bladder and bowel dysfunction, and variable lower extremity involvement. The difference from the conus medullaris syndrome is the absence of upper motor neuron signs, and it is usually characterized by asymmetric lower extremity weakness and reflex changes. It is believed to have a better prognosis for neurologic recovery than SCI because nerve roots have the ability to regenerate. Important predictors for favorable outcome from cauda equina are early diagnosis and surgical decompression.

ACUTE MEDICAL MANAGEMENT

The acute management of patients with SCI is primarily directed at medical stabilization to prevent secondary injury and to permit the accurate clinical and radiographic diagnosis of spinal cord and column pathology. The specifics of initial management have been detailed to some degree in the earlier section covering diagnosis of SCI, as the acute management and evaluation of SCI are intertwined.

General Trauma Care

In general, patients should be managed at a trauma center, preferably level 1, with SCI experience. If an appropriate trauma center is not immediately available, transfer to a trauma center as soon as possible is advocated. Emergency medical services in urban areas should preferentially take patients to level 1 centers, potentially bypassing nearer hospitals. Level 1 centers are required to have in-house neurosurgical consultation for rapid evaluation. The patient should be immobilized with a cervical collar and backboard/headstrap as soon as possible. The backboard can be removed after radiographic studies are completed and interpreted. The cervical collar should be maintained until the cervical spine has been clinically and/or radiographically cleared. Neurosurgical evaluation should happen as soon as possible; neural element decompression and spinal stabilization within 24 hours may improve neurologic recovery in patients with deficits and spinal cord compression, but the clinical data are inadequate to advocate this as a standard of care. It is important to note that there has been no demonstrated increased risk of neurologic deterioration from early surgery.

Steroids

High-dose methylprednisolone has long been considered a potential neuroprotective agent in SCI, with the potential of reducing tissue injury by inhibiting lipid peroxidase and free radical production. Methylprednisolone therapy was evaluated in 487 SCI patients in the National Acute Spinal Cord Injury Study II (NASCIS II) trial in 1990. Patients were given a bolus of 30 mg/kg of methylprednisolone over 15 minutes, followed by a 5.4-mg/kg infusion over 23 hours. The authors reported a mean improvement of 5 points in motor score (total possible score = 50) and 4 points in sensory scores (total possible score = 58) for patients treated with methylprednisolone compared to controls at 6 months, but only if they received the drug within 8 hours of injury. Although NASCIS II was initially reported as a positive trial, reanalysis has showed that the strength of the evidence generated is weakened by omission of data from publication, the arbitrary assignment of an 8-hour therapeutic window, the inconsistency of reported benefit, and the absence of functional outcome measures. Accordingly, the beneficial results of NASCIS II have been downgraded to class III medical evidence. Due to a trend toward more serious complications associated with steroid use, current guidelines do not recommend administration of methylprednisolone for the treatment of acute SCI LEVEL 3.[3]

Autonomic Dysfunction and Blood Pressure Management

Autonomic dysfunction with hypotension can occur acutely in SCI, especially in patients with cervical injuries. Autonomic dysfunction may result from a variety of reasons including the following: spinal shock, neurogenic shock, hypovolemia, bradycardia, sepsis, and cardiogenic shock. Hypotension is a common contributor to secondary neurologic injury and should be avoided; its treatment can involve careful volume resuscitation, vasopressors, and diagnostic maneuvers such as an arterial line, a central venous catheter, and noninvasive continuous cardiac output assessment. *Current SCI guidelines recommend maintenance of mean arterial pressure at a minimum value of 85 to 90 mm Hg for the first 7 days after injury.* This has limited supporting clinical data, but hypotension clearly should be avoided. Occasionally, intravenous (IV) atropine sulfate may be necessary to counter unopposed parasympathetic activity. Vasomotor paralysis may also cause loss of thermal control and lead to poikilothermy,

which usually may be treated by the appropriate use of warming blankets. Acute cervical SCI is also associated with a risk of cardiac arrhythmia due to excess vagal tone as well as complicating hypoxia, hypotension, and fluid and electrolyte imbalances.

Critical Care

After complete medical stabilization, neurologic assessment, and spinal column stabilization and/or bracing within the initial 24 to 48 hours, attention is paid to the prevention of common medical problems in patients with acute SCI. Prophylactic treatment for deep venous thrombosis should begin no later than 72 hours after SCI. The first-line therapy is subcutaneous injection of low molecular weight heparin (enoxaparin 40 mg subcutaneously every day), and second-line therapy is subcutaneous injection of unfractionated heparin (5,000 U subcutaneously two or three times a day). In patients with contraindications to anticoagulation, an inferior vena cava filter should be placed to prevent pulmonary embolism. Lower extremity sequential compression devices should also be employed when feasible. Stress ulceration should be prevented with proton pump inhibitors or H_2 blockers with a minimum of 4 weeks of therapy after SCI. Nutritional support, via feeding tubes or parenteral nutrition if appropriate, is suggested to begin with 72 hours after SCI. Pressure ulcers of the occiput, sacrum, and heels should be prevented through manual or automatic turning every 2 hours without lateral sliding to prevent sacral shearing. Rehabilitation maneuvers should begin as soon as possible and should include passive and active range-of-motion (ROM) activities, bowel and bladder programs (eg, chronic intermittent catheterizations), pulmonary programs (mechanical ventilation, manually assisted cough), and dysphagia evaluations.

Surgical Treatment

After control of the acute medical issues and accurate neurologic and radiographic diagnosis of SCI, attention is directed toward treating instability of the vertebral column and neural element compression, if present. This is directed by neurosurgical or orthopedic caregivers. There are currently no standards and no evidence-based guidelines regarding the role and method of decompression in acute SCI. In a recent prospective randomized trial, decompression of cervical spinal cord injuries within 24 hours of injury was found to be safe and associated with improved neurologic outcome at 6 months follow-up when compared to more delayed surgical intervention LEVEL 2.[4] Multiple observational cohort studies have confirmed that emergency decompressive surgery performed within 24 hours for incomplete injuries (ASIA B, C, and D) results in improved motor recovery and reduced hospital length of stay. The management of cervical, thoracic, and lumbar spine and spinal cord injuries depends mainly on the particular injury but also on a surgeon's personal experience and practice norms in his or her center. The options include closed reduction via traction and open surgical procedures. The overall goals are to decompress the spinal cord and nerve roots, to restore the spinal alignment, and to prevent progressive deformity.

Cervical spine fracture or dislocations may be treated with closed reduction through the use of traction. Thoracic and lumbar fractures cannot be corrected with this treatment. Traction uses skull tongs or the headpiece of a halo attached to a system to apply rostral force, usually with rope, a pulley, and weights. An initial weight of 5 to 15 lb is applied, and a lateral x-ray is obtained. Weight can be increased at 5-lb increments, and a neurologic exam and lateral x-ray should be obtained after each adjustment. The maximum weight applied relates to the level of injury. A general rule of 3 to 5 lb per vertebral level is used. We suggest that after 35 lb is applied, patients be observed for at least an hour with repeat cervical spine x-rays before the weight is cautiously increased further. Muscle relaxants and analgesics may help facilitate reduction.

Cervical spine surgery is indicated for injuries that are not amenable or do not respond to closed reduction. These include unstable cervical fractures and cord compression with an incomplete neurologic deficit. Patients without neurologic deficits are often treated nonoperatively with bracing unless there is evidence of instability. Some penetrating injuries may require surgical exploration to ensure that there are no foreign bodies imbedded in the tissue and also to clean the wound to prevent infection.

Thoracolumbar injuries do not lend themselves to external traction, and accordingly, surgical repair is typically achieved through open reduction followed by stabilization. There are a variety of anterior and posterior approaches that employ metallic implants such as interbody cages, pedicle screws, laminar wires or hooks, and connecting rods.

In clinical studies, surgery has little effect on the neurologic outcome of the primary injury. When cord compression is evident, or the initial neurologic deficit progresses, immediate decompression (ie, 1-2 h after injury) may halt or reverse the process. There are no set rules for determining appropriate selection of early or late surgical intervention. Individual patient factors and clinical judgment continue to direct the surgical timing in each case.

CHRONIC MEDICAL MANAGEMENT

Chronic medical therapy is directed at preventing and treating the common, and often severe, medical complications of SCI. SCI produces a wide variety of changes in systemic physiology that can lead to a number of complications, which rival the impact of neurologic deficits on function and quality of life. In the National Spinal Cord Injury database, rehospitalizations occurred in 55% of patients in the first year after SCI and continued at a stable rate of about 37% per year over the next 20 years. Factors contributing to the risk of rehospitalization included increased age and severity of SCI. Genitourinary problems, respiratory complications, and pressure ulcers were the most common reasons for hospitalization. As mentioned earlier, life expectancy is reduced among patients with SCI. The mortality rates are highest during the first year. Higher injury levels, more severe injury, and older age correlate with higher mortality. The most common causes of death are respiratory diseases and cardiovascular events.

Pain

Pain is a serious consequence of SCI. Approximately 80% of patients reported pain at all times during the first year after injury. Neuropathic pain related to SCI increases over time, whereas musculoskeletal pain decreases slightly, with both still being present in 60% of patients at 1 year. Early (1 mo) sensory hypersensitivity (particularly cold-evoked dysesthesia) is a predictor of the development of below-level, but not at-level, SCI pain at 1 year.

Management of pain should focus on the avoidance of chronic opioid abuse, judicious use of nonsteroidal anti-inflammatory agents for chronic musculoskeletal pain, and appropriate agents for treatment of central neuropathic pain (see Chapter 59).

Autonomic Dysreflexia

Injuries above T6 may be complicated by autonomic dysreflexia, which results from the loss of coordinated autonomic responses to physiologic stimuli. Uninhibited or exaggerated sympathetic responses to noxious stimuli can lead to extreme hypertension through vasoconstriction. The parasympathetic system will respond with vasodilation and bradycardia above the level of the lesion, but it is not sufficient to correct the elevated blood pressure (BP). SCIs below T6 do not produce dramatic effects as the intact splanchnic innervation allows for compensatory dilatation of the splanchnic vascular bed.

Typical stimuli producing autonomic dysreflexia include bladder distention, bowel impaction, pressure sores, bone fractures, or occult visceral disturbances.

Common clinical manifestations are hypertension, bradycardia, headache, and sweating. Attacks have a range of severity from asymptomatic hypertension to hypertensive crisis with possible cardiac arrest from bradycardia and intracranial hemorrhage. The severity of attacks correlates with the severity of the SCI. The management of acute autonomic dysreflexia involves monitoring BP, removing tight-fitting garments, and searching for sources of noxious stimuli, including bladder distension and fecal impaction. Reduction of elevated BP can be achieved with sitting the patient upright and with rapid-acting antihypertensives with short half-lives. Sublingual or oral nitrates and IV β-blockers, calcium channel blockers, or angiotensin-converting enzyme inhibitors are often used. Recognition and avoidance of inciting stimuli are important in preventing attacks.

Orthostatic hypotension can also affect patients with SCI. Treatment involves the implementation of temporary maneuvers, such as gradual position changes, compression stockings, and abdominal binders, until the body adapts to the loss of peripheral tone. Medical therapy, if necessary, can include salt tablets to increase blood volume, α-adrenergic agonists, such as midodrine, or mineralocorticoid supplements, such as fludrocortisone.

Coronary Artery Disease

Coronary artery disease (CAD) is a prominent complication of SCI with long-term survivors. Patients with SCI are more likely to acquire CAD risk factors than the average population secondary to loss of muscle mass, inactivity, and increased body fat. CAD is 3 to 10 times more likely in patients with chronic SCI, and SCI patients have higher mortality rates with CAD-related events. This is partly explained by abnormal presentations that occur in patients with lesions higher than T5 and the higher likelihood of episodic autonomic dysreflexia.

Pulmonary Disease

Cervical and high thoracic SCI will affect respiration. The severity of respiratory failure and need for assisted ventilation is directly related to the level and severity of SCI. Patients have impaired cough strength and difficulty mobilizing lung secretions and are at increased risk for pneumonia, especially during the first year following injury (see also Chapter 121). Prevention of pneumonia includes chest physiotherapy and pneumococcal vaccination. Deep venous thrombosis and pulmonary embolism are common early complications of SCI. Prophylactic use of low molecular weight heparin is the treatment of choice for most patients with SCI; treatment should be continued for at least 3 months after SCI, after which the risk appears to approximate that of the general population.

Genitourinary Complications

SCI produces bladder dysfunction, often referred to as the *neurogenic bladder* (see also Chapter 126). Other complications can result from this, including infections, vesicoureteral reflux, renal failure, and nephrocalculi. Urologic evaluation with regular follow-up is recommended for patients after SCI. Genitourinary complications may not produce symptoms and, if untreated, can have serious consequences. The frequency and specific testing involved (serum creatinine, cystoscopy, urodynamic studies, renal ultrasound) are not well defined but depend in part on the nature of the patient's urologic problems and other risk factors.

After SCI, the sensation for bladder fullness as well as motor control of bladder and sphincter function can be impaired. Depending on the timing, the level, and the severity of injury, one of several types of bladder dysfunction can occur. These include bladder hyperactivity with reflexive bladder emptying, sphincter hyperactivity with impaired emptying of the bladder, detrusor-sphincter dyssynergia leading to uncoordinated bladder contractions, bladder flaccidity with urinary retention, and overflow incontinence.

Clean intermittent catheterization programs achieve the goal of preserving renal function while eliminating urine at regular and socially acceptable times. This avoids high bladder pressures, retention, incontinence, and infection. This should be initiated as early as possible after SCI. Catheterization is performed approximately every 4 hours and is adjusted as necessary. Often, patients have a fluid intake restriction of 2 L to prevent bladder overdistention. After ruling out an infection and adjusting the frequency of clean intermittent catheterization and fluid intake, medications targeting the sympathetic and parasympathetic receptors are employed depending on the specific bladder condition.

Urinary tract infections are common in SCI and are the most frequent source of septicemia in SCI patients. Asymptomatic urinary tract infections are not generally treated, and prophylactic antibiotics are not used for prevention.

Sexual dysfunction has a high prevalence in SCI; dysfunction in males can exceed 75% and is related to the severity of injury. There are a variety of treatment options for men with SCI, which include medicines for erectile dysfunction and surgically implanted prosthetics. Sexual responses in women may also be impaired after SCI, but ovulation and fertility are generally unaffected. Pregnancy with SCI is considered high risk because of the high rate of complications secondary to infections and autonomic dysreflexia.

Gastrointestinal Dysfunction

Bowel dysfunction is very common after SCI and can significantly affect quality of life. There are no evidence-based recommendations for clinical management of this problem. A structured bowel regimen employing a regular diet, 2 to 3 L of fluid per day, 30 g of fiber, and chemical and mechanical stimulation is often employed to achieve predictable bowel evacuation to avoid fecal incontinence and impaction.

Abnormal Bone Metabolism

Osteoporosis can affect the bones below the level of SCI, most likely secondary to disuse, and may predispose to fractures. Bone resorption in the first few months after SCI can lead to symptomatic hypercalcemia. Treatment can involve the use of hydration with IV fluids, loop diuretics, and IV bisphosphonate therapy.

Heterotopic ossification, the deposition of bone within the soft tissue around peripheral joints, can also occur in SCI. This occurs in up to half of SCI patients but is symptomatic, as evidenced by pain and inflammation in the affected joints, in 10% to 20% of patients. Treatment involves passive ROM exercise, oral bisphosphonates, nonsteroidal anti-inflammatory drugs, and, in some cases, delayed surgery.

Spasticity

Problematic spasticity requiring treatment occurs in approximately 35% of SCI patients during the first year of recovery. Patients with incomplete ASIA C injuries appear to be at highest risk. Spasticity results from the disruption of the descending inhibitory pathways with a concomitant increase in the excitability of spinal reflexes and resting muscle tone. Spasticity can negatively affect quality of life through pain, decreased mobility, muscle spasms, and ultimately contractures. Prevention of contractures involves proper positioning, passive ROM exercises, appropriate splinting, and treatment of spasticity. However, the increased tone can also make some activities easier, such as standing and transfers. Treatment can include physical therapy, passive ROM exercises, oral medications (baclofen, tizanidine, valium, etc), and surgical interventions (intrathecal baclofen pumps, rhizotomies, etc).

Psychiatric Complications

Psychiatric disorders associated with SCI include depression, suicide, and drug addiction. Approximately a third of patients with SCI will be depressed within the first year after SCI; this is not closely associated with severity of injury. Suicide occurs at a rate 4 to 5 times higher in patients with SCI and is the leading cause of death in patients with SCI younger than the age of 55 years. Patients should be regularly screened for symptoms of depression, and symptoms should be treated immediately.

CONCLUSION

SCI remains a difficult medical, social, and financial problem. A more clear understanding of the pathophysiology and resultant medical complications has resulted in improved long-term survival and functional status. However, the unsolved problem of SCI repair remains. It is worth remembering that the best treatment is prevention. Nationwide educational programs should be concerned with combating the causes of SCI: motor vehicle safety, water and occupational safety, eliminating drunk driving, adhering to speed limits, and mandatory use of seatbelts and other protective gear.

49 Traumatic Cranial and Peripheral Nerve Injury

Dominique M. O. Higgins, Lillian Liao, and Christopher J. Winfree

KEY POINTS

1. The olfactory nerve, facial nerve, and cranial nerves responsible for ocular movement are the most likely to be associated with head trauma.
2. Peripheral nerve injuries can be classified into three main categories: neuropraxia, axonotmesis, and neurotmesis.
3. Electrodiagnostic evaluations are critical for establishing the severity, location, and prognosis of peripheral nerve lesions.
4. Generally, for peripheral nerve injuries, acute surgical intervention should be avoided.
5. Spontaneous recovery should be looked for initially if there is no evidence of sharp nerve transection or acute nerve compression
6. Depending on the mechanism of injury, functional connectivity can be achieved surgically by scar tissue removal, reapproximation, or placement of interposition grafts.

INTRODUCTION

Traumatic injury to peripheral nerves is associated with significant disability and decreased quality of life. In this chapter, we discuss the classification, pathophysiology, evaluation, and treatment of peripheral nerve injuries as well as the clinical manifestations of common peripheral and cranial nerve lesions. Understanding of the principles described in this chapter, by clinicians, is important for timely diagnosis and treatment of these common clinical entities.

It has been estimated that approximately 3% to 10% of all patients presenting to a Level 1 trauma center present with injury to a peripheral nerve. Motor vehicle accidents are most commonly cited as the leading cause, whereas industrial accidents, recreational vehicle use, falls, gunshot, and stab wounds as well as iatrogenic injuries also contribute. The potential economic and social impact of these injuries is compounded by the fact that they occur most commonly within the productive age range, with highest incidence reported between 20 and 40 years of age. Males are affected more often than females, and injury to the nerves of the upper extremity occur more commonly than do those to the nerves of the lower extremity. Peripheral nerve injuries are also commonly comorbid with traumatic injury to the brain, which can result in delayed diagnosis and intervention.

Anatomy and Physiology

Evaluation of traumatic peripheral nerve injury requires understanding of nerve structure. Peripheral nerves consist of a mixture of myelinated and unmyelinated, somatic and autonomic, nerve fibers. Each fiber is surrounded by an endoneurial sheath, which provides some tensile strength. Multiple fibers, of various types, are grouped together into fascicles and surrounded by the perineurium, a specialized structure composed of perineurial cells and collagen that serves to maintain homeostasis of the endoneurial fluid that surrounds individual fibers. This perineurial sheath provides most of the tensile strength and elasticity of the nerve and provides a diffusion barrier that resists and maintains intrafascicular pressure. Multiple fasciculi, in turn, are embedded in a connective tissue matrix called the *epineurium*, which protects the nerve from compression. The most superficial layer of the epineurium condenses to form an external epineural sheath, which gives the nerve a cord-like appearance on gross examination.

Both within and between nerve fibers, the number, size, and organization of fascicles varies significantly. As fascicles branch, split, and rejoin continuously along their course, sections through the nerve may alternatively reveal plexiform and cable-like structure, which has implications for both clinical presentation of nerve injuries as well as surgical repair and functional regeneration. Furthermore, variability in internal organization is partially responsible for observed differences in the prevalence of particular nerve injuries. That is, peripheral nerves with a higher proportion of epineural tissue to fasciculi may be more resistant to compression injuries, whereas peripheral nerves with greater numbers of fasciculi have greater tensile strength.

Mechanisms of Injury

Traumatic nerve injuries may be acute or chronic and iatrogenic or idiopathic. They result from the application of kinetic energy to a nerve, which is transformed into damaging compressive or tensile forces. Chronic traumatic nerve injuries most often result from anatomic nerve entrapment leading to well-described clinical entities, such as carpal tunnel syndrome. These chronic syndromes, requiring unique medical and surgical treatment approaches, are discussed more thoroughly in other chapters.

Acute traumatic nerve injuries occur, most commonly, from traction/stretch, compression, contusion, laceration, or ischemia. Injury is derived primarily from direct application of mechanical forces and secondarily from vascular compromise. Multiple mechanisms of injury may be present, particularly when the lesion occurs during a catastrophic event, such as a motor vehicle accident. Identifying the type of insult incurred, when possible, is important for treatment planning because various types of forces result in different patterns of injury.

TABLE 49.1 Seddon's Nerve Injury Classifications and Prognosis

Class	Pathology	Mechanism	Treatment	Prognosis	Time Course
Neurapraxia	Demyelination	Compression Ischemia	Medical Physical therapy	Excellent	Hours to 3 mo
Axonotmesis	Axonal disruption Distal degeneration Epineurium intact	Crush Stretch Percussion	Variable: may require surgery	Variable: good to poor	Weeks to years
Neurotmesis	Complete loss of continuity Transection Distal degeneration	Sharp injuries Traction	Surgical: end-to-end neurorrhaphy, grafting, or neurotization	Poor/nil without repair	Months to years with surgery No spontaneous recovery

Injury Classification

Two major classifications systems are used most commonly to describe peripheral nerve injuries. The injury categories defined by these systems each have unique diagnostic characteristics, prognoses, and therapeutic approaches.

The classification system used most commonly in clinical settings was proposed by Seddon in 1942. Seddon's system divides injuries into three main categories delineated by the extent of disruption to the structure of the nerve. The three categories are *neurapraxia*, *axonotmesis*, and *neurotmesis* (**Table 49.1**).

Neurapraxia is the least severe of the three injury types. It most commonly is caused by a mild insult resulting in focal demyelination with no associated axonal degeneration. It is characterized by transient focal conduction block across the lesion. The axon distal to the site of injury remains intact, and the nerve remains in continuity. Clinically, this class of injury may manifest as weakness or sensory loss in the anatomic distribution of the affected nerve. Prognosis for this type of injury is excellent, with spontaneous recovery occurring within hours to, in the most severe cases, a few months. No specific therapeutic intervention is required.

Axonotmesis occurs most commonly during crush, stretch, or percussive injuries, such as gunshot wounds where injury is most commonly caused by indirect heat and shock wave from the bullet rather than transection. These injuries result in irreversible damage to axonal elements including the myelin sheath, leading to distal degeneration. Supporting structures such as the epineurium, perineurium, and, at times, the endoneurium remain intact.

Prognosis for axonotmetic injuries depends on several factors. These factors include the degree of disruption of the internal structure of the nerve as well as distance from the end organ and the particular characteristics of the injured nerve. Spontaneous recovery is possible after axonotmetic injury, but the time course is considerably greater than that of neurapraxic lesions. Recovery is more commonly partial than complete.

Neurotmesis is defined by complete loss of continuity of the nerve. All connective tissue layers, the axon, and the myelin sheath are irreversibly damaged. Surgical intervention is required because no spontaneous recovery is possible. The timing of surgery is dependent on the mechanism of injury because blunt injuries continue to evolve through an inflammatory process over a period of weeks. Prognosis after surgery is variable but is generally poorer than that of spontaneous recovery.

A second important peripheral nerve injury classification system was proposed by Sunderland in 1951 (**Table 49.2**). Expanding on the work of Seddon, he described five classes of nerve injury, with class I describing neurapraxic lesions and class V equivalent to neurotmesis. For classes II to IV, Sunderland subdivided axonotmesis into three levels, of increasing severity and worsening prognosis, based on the extent of internal disruption, from axon only in class II to endoneurial sheath in class III and perineurium in class IV. Although this additional level of detail is helpful in a research setting, the clinical use is more limited because all classes II to IV will require the same initial therapeutic approach. Nevertheless, this classification scheme highlights the importance of internal nerve structure for spontaneous recovery and functional regeneration.

TABLE 49.2 Sunderland's Classification of Peripheral Nerve Injuries

Class	Pathology	Mechanism	Treatment	Prognosis	Time Course
I	Demyelination	Compression Ischemia	Medical Physical therapy	Excellent	Hours to 3 mo
II	Axonal disruption Distal degeneration	Crush Stretch Percussion	Variable	Good	Months to years
III	II + endoneurial disruption	Crush Stretch Percussion	Variable	Moderate	Months to years
IV	III + perineurial disruption	Crush Stretch Percussion Traction	Variable	Poor without repair	Months to years
V	Complete transection	Sharp injury Traction	Surgery	Poor/nil without repair	Months to years with surgery No spontaneous recovery

Repair and Regeneration

Characteristic pathologic changes in the nerve occur as a result of traumatic insult. In the mildest form, demyelination is observed at the injury site. When trauma results in axonal disruption, the distal nerve undergoes a process of degeneration that extends to the end organ. The duration of the degenerative process is dependent on the distance of the injury from the end organ. Morphologic and functional changes also take place within the proximal stump adjacent to the injury site.

In the initial period immediately following injury, acute axonal degeneration, extending approximately 300 mm proximally and distally from the lesion site, is triggered by an influx of extracellular calcium. On electron microscopy, vacuoles resembling autophagosomes accumulate in the axon ends. Swelling and disruption of neurofilaments is observed.

These immediate changes are followed by fragmentation and phagocytosis of the myelin sheath. Within 2 days, whorls of myelin debris and small lipid droplets may be observed within the Schwann cells. Circulating macrophages are recruited and enter the distal stump. Loss of axonal contact and the presence of macrophages stimulate Schwann cell proliferation and dedifferentiation. These dedifferentiated Schwann cells line up along the basal lamina to form bands of Büngner, which will act as guides to regenerating nerve axons.

Reinnervation occurs via two main mechanisms: collateral axonal sprouting from uninjured axons and axonal regeneration, which occurs spontaneously from the proximal stump following degeneration. Collateral sprouting is an early mechanism of functional motor recovery. It occurs with incomplete lesions, in which some of the axons remain intact. New axonal outgrowths are noted to arise from both nearby nodes and terminal branches. These fine axonal extensions travel along the remaining nerve structures to provide partial reinnervation to nearby motor targets. Generally, collateral sprouting is not sufficient to restore full power to the muscle but may be responsible for some early functional recovery.

Axonal regeneration is the primary mechanism by which reinnervation occurs, following distal degeneration, in axonotmetic and neurotmetic lesions. Regeneration begins from the proximal stump and extends along intact basal lamina toward the end organ at a variable rate of approximately 1 to 2 mm/d. Once the target organ has been reached, a process of maturation occurs to reestablish functional connections. The appearance of clinical evidence of reinnervation reflects both the distance from injury site to the end organ and the maturation process. Rate of regeneration appears to be slower for transected lesions than for crush injuries.

Successful regeneration and functional recovery rely on a number of factors. Inflammation and scar tissue provide major barriers to axonal growth. Gap lengths that are too long result in disorganized and highly tortuous axonal paths, which may coalesce within scar tissue to form a nonfunctional and potentially painful bulb referred to as a *neuroma*.

Even when regeneration does occur successfully, functional recovery is not guaranteed. Regenerating sprouts must be able to form mature connections with appropriate motor or sensory targets in order for recovery to occur. In highly mixed nerves, with an approximately equal amount of sensory and motor fibers, some regenerating motor fibers may be lost to sensory targets or vice versa. Nerves that contain one predominant modality generally have a better prognosis for functional recovery.

Finally, sensory targets maintain viability for a much longer period of time than does muscle tissue. Within 12 to 18 months, fibrotic changes take place in denervated muscle that makes successful reinnervation unlikely. Sensory targets, on the other hand, maintain viability for up to 2 to 3 years. Therefore, patients may continue to experience recovery of sensation well beyond the period of motor recovery.

CLINICAL FEATURES

The clinical manifestation of traumatic peripheral nerve injury depends on the mode, location, and extent of the injury sustained. Signs and symptoms reflect both the location and severity of the lesion as well as the composition of the injured nerve. Injury to a nerve that consists predominantly of motor fibers will manifest as weakness or paralysis and atrophy in the corresponding myotomal distribution. Injury to a predominantly sensory nerve, on the other hand, will present with sensory alteration or loss in the corresponding dermatomes. Autonomic and trophic function may also be affected resulting in decreased sweating, hair loss, and skin changes in the affected region. Partial lesions and faulty regeneration may result in the development of difficult to treat pain, often described as "pins and needles," stabbing or burning in character. For some patients, a debilitating symptom complex called *complex regional pain syndrome II*, also referred to as *causalgia*, may develop, which is characterized by allodynia, autonomic dysregulation, and maladaptive neuroplastic changes in central nervous system response to and processing of pain signals. This syndrome often does not respond well to conventional pain management strategies.

Some common associations are seen between various injury mechanisms and specific peripheral nerves. Awareness by clinicians, of these associations, may contribute to the earlier identification and treatment of potentially disabling injuries. Some of these common associations and their clinical presentations are discussed in the following section.

Cranial Nerve Lesions

Acute injury to cranial nerves often accompanies trauma to the head and neck. Significant injury may occur even with mild head trauma. One study by Coello and colleagues that evaluated cranial nerve function in 16,440 mild head trauma patients, defined by a Glasgow Coma Scale score of 14 or 15 at the time of presentation, over a period of 6 years, found a prevalence of associated cranial nerve injury of 0.3%, with the olfactory nerve being the most commonly affected, followed by the facial nerves and the nerves responsible for ocular movement. Injury to the lower cranial nerves (IX-XII) was noted to occur less frequently as a consequence of head trauma but to be more closely associated with iatrogenic injury during various medical and surgical interventions. The prevalence, location, and type of cranial nerve injuries observed most frequently result from the specific anatomic vulnerabilities of the affected nerve (**Table 49.3**).

Cranial Nerve I: The Olfactory Nerve

The olfactory nerve, responsible for our ability to detect and distinguish smells, is one of the most commonly cited cranial nerves to be injured as a result of head trauma. Olfactory dysfunction has been reported to occur in up to 4% to 7% of all cases of head trauma. Injury may occur at multiple sites along

TABLE 49.3 Cranial Nerve Injury, Mechanisms, and Presentation

Cranial Nerve	Type of Injury	Mechanism of Injury	Clinical Presentation
I: Olfactory	Head trauma from acceleration-deceleration forces (eg, MVAs)	Shearing of olfactory nerve ligaments crossing cribriform plate Contusion of olfactory bulb against frontal bone Damage of cortical olfactory tract by edema, hemorrhage, or ischemic injury of orbitofrontal and temporal lobes	Anosmia Parosmia Impaired perception of taste
II: Optic	Direct Indirect Complication of facial fracture repair for maxillofacial trauma	Anatomic disruption of nerve fibers by fracture fragments, penetrating trauma, or hematoma within nerve sheath Transmission of forces to optic canal during blunt head trauma Direct intraoperative nerve injury, retinal vascular occlusion from orbital edema, increased intraorbital pressure in optic canal	Visual acuity impairment
III: Oculomotor	Compressive • Expanding hematoma • Uncal herniation • Aneurysm of posterior communicating artery aneurysm Ischemic	Compression of parasympathetic fibers running along outside of nerve	Pupillary constriction deficit (mydriasis) more likely first Motor deficit more likely first • "Down and out" eye deviation • Ptosis • Loss of pupillary constriction to light but not accommodation
IV: Trochlear	Dorsal midbrain hemorrhage Complication of dental anesthesia during upper molar surgery (rare)	Direct injury to the trochlear nerve or its brainstem nucleus.	Inclining head toward unaffected eye (unable to move eye medially and inferiorly) Other oculomotor and neurologic deficits
VI: Abducens	Cranial base fracture, clival epidural hematoma Cervical hyperextension, atlanto-occipital dislocation, hyperflexion	Downward displacement against petrous ridge at turning point to enter into Dorello canal	Severe double vision Medial deviation of affected eye
V: Trigeminal	Iatrogenic • Dental/cranial trauma • Supraglottic airway devices	Compression of lingual nerve	Temporary loss of sensation and taste in anterior tongue (resolves within 6-9 wk)
VII: Facial	Intracranial lesion Lesion in facial canal of temporal bone Extracranial lesion	Direct injury to the facial nerve.	Impaired movement of facial muscles, taste from anterior two-thirds of tongue, salivation, lacrimation, hyperacusis (less common) Lacrimation may be spared Motor deficits
IX: Glossopharyngeal	Trauma	Fracture at jugular foramen where IX, X, and XI exit (rarely isolated)	Diminished taste in posterior one-third of tongue Loss of gag reflex on side of lesion
X: Vagus	Injury to pharyngeal branches Injury to superior/recurrent laryngeal branches	Fracture at jugular foramen where IX, X, and XI exit (rarely isolated).	Dysphagia Dysarthria Palate on affected side low at rest Deviation of uvula toward unaffected side with phonation
XI: Spinal Accessory	Trauma Iatrogenic • Lymph node biopsy • Internal jugular central venous line placement • Carotid endarterectomy	Fracture at jugular foramen where IX, X, and XI exit (rarely isolated) Extracranial lesion as nerve passes through posterior triangle of neck	Atrophy of upper trapezius Inability to shrug affected shoulder Impairment in head rotation to contralateral side Scapular winging at rest (worsened by abduction)
XII: Hypoglossal	Iatrogenic • Carotid endarterectomy • Endotracheal intubation • Supraglottic airway device Trauma	Fracture of occipital condyle	Dysarthria Deviation of tongue toward side of lesion

Abbreviation: MVA, motor vehicle accident.

the olfactory pathway. It is most often associated with acceleration-deceleration forces, such as those generated during motor vehicle accidents. Common injury sites include the olfactory nerve filaments as they cross the cribriform plate and are subject to shearing forces; the olfactory bulb, which may be contused against the frontal bone; and the cortical olfactory tracts, which may be damaged by edema, hemorrhage, or ischemic injury of the orbitofrontal and temporal lobes. *Anosmia*, the complete loss of odor detection, is the most common clinical finding, but *parosmia*, a decrease in olfaction acuity, is also observed, particularly with injury to the temporal lobe. The perception of taste, which is reliant on olfaction, is also commonly impaired in patients with injury to the olfactory nerve, and it is this symptom for treatment of which most patients present.

Despite the relative frequency with which injury to the olfactory nerve occurs following head trauma, deficits are rarely identified in the acute period. This may be because of the fact that trauma patients present with multiple injuries of varying severity and immediacy that require disproportionate allocation of resources. Nevertheless, loss of olfaction may have significant impact on quality of life, resulting in diminishment of enjoyment of food and other sensual experiences reliant on smell; loss of employment, when dependent on the sense of smell or taste; and decreased ability to detect environmental cues that may signal danger, such as the odor of volatile gas or fire. Awareness by clinicians of the association of head trauma with cranial nerve I dysfunction is important for early detection and diagnosis.

Cranial Nerve II: The Optic Nerve

Traumatic optic neuropathy, which may result in complete or partial loss of visual acuity in the affected eye, has been reported to occur in 1.4% to 5% of head trauma cases. Injury may be *direct*, resulting from anatomic disruption of nerve fibers by fracture fragments, penetrating trauma, or hematoma within the nerve sheath, or *indirect*, reflecting the transmission of forces to the optic canal during blunt head trauma. Early decompressive surgery may be required to prevent irreversible vision loss.

Additionally, injury to the optic nerve is recognized as a potential complication of facial fracture repair in patients with maxillofacial trauma, with a reported incidence of 0.3%. Mechanisms include direct intraoperative nerve injury, retinal vascular occlusion from orbital edema, and increased intraorbital pressure in the optic canal resulting in indirect injury to the nerve. This complication is most often reported after surgical intervention of the orbital floor, and ischemia is the most common final pathway leading to injury.

Unlike skeletal tissues, the optic nerve and retinal tissues are extremely sensitive to hypoxia and pressure, with irreversible ischemic damage occurring within 60 minutes to 2 hours. Because of this sensitivity, prompt identification of even subtle changes in visual acuity by the clinician is essential to provide potentially vision-sparing interventions in a timely manner.

Cranial Nerve III, IV, VI: The Oculomotor, Trochlear, and Abducens Nerves

Together, the oculomotor, trochlear, and abducens nerves innervate the muscles responsible for ocular movements. Damage to these nerves is a common complication of closed head injury. It may result in diplopia, impairments in eye movement, and ocular deviation. Injury to the nerves may occur at the nuclei in the brainstem, as the nerve exits the brainstem, and at the point where it pierces the dura mater. The site of injury reflects both the injury mechanism and the anatomic characteristics of the nerve. One or all of the nerves for oculomotor control may be affected, and clinical presentation will vary accordingly.

Cranial nerve III, the oculomotor nerve, innervates many of the muscles responsible for eye movement, including the medial rectus, superior rectus, inferior rectus, inferior oblique, levator palpebrae superior, and the pupillary constrictor. Additionally, the oculomotor nerve carries parasympathetic fibers to the eye. Complete lesion of this nerve results in a "down and out" deviation of the eye, ptosis, dilation of the pupil, and loss of pupillary constriction to light but not accommodation. Partial lesions may result in any combination of these findings, depending on the specific nerve fibers affected. Because the parasympathetic fibers run along the outside of the nerve, compressive lesions, such as an expanding hematoma or progressive uncal herniation secondary to intracranial hemorrhage or edema, tend to present with pupillary changes first, which may progress to oculomotor palsy with increasing pressure. Aneurysms of the posterior communicating artery may also compress the third cranial nerve and should be considered when evaluating a patient with oculomotor nerve palsy. Injuries that cause third nerve ischemia, on the other hand, are more likely to affect the motor fibers before disrupting the parasympathetic components. This distinction may help the clinician to identify the etiology of idiopathic third nerve palsy.

The trochlear nerve provides innervation to the superior oblique muscle. Lesion of this nerve results in an inability to move the eye medially and inferiorly. The resulting diplopia may be resolved by inclining the head toward the unaffected eye. Trochlear nerve palsies occurring in isolation have been observed following dorsal midbrain hemorrhage and as a complication of dental anesthesia during upper molar surgery but are extremely rare. Generally, injury to the fourth cranial nerve is accompanied by other oculomotor and neurologic deficits.

The abducens nerve innervates the lateral rectus muscle, which is responsible for abduction of the eye. Injury to this nerve results in severe double vision in almost all gaze directions and medial deviation. Traumatic injury to the sixth cranial nerve has been associated with cranial base fracture and the development of clival epidural hematoma as well as cervical hyperextension, atlanto-occipital dislocation, and hyperflexion. The sixth cranial nerve vulnerability to injury is thought to be a result of its long and delicate intracranial source. After exiting the pons, it ascends vertically within the subarachnoid space for 15 mm before piercing the dura mater. From there, the nerve travels over the ridge of the petrous bone and changes directions abruptly at a 120° angle to enter Dorello canal, which is a triangular space defined by the apex of the petrous bone the posterior clinoidal process, and Gruber ligament, a thickened portion of the dura mater that connects the two. The nerve is tethered by the dura on either side of the canal. From Dorello canal, the nerve passes through the cavernous sinus and the superior orbital fissure to reach the lateral rectus muscle. Traumatic injury to the abducens nerve is thought to occur most commonly by downward displacement against the petrous ridge at the point at which it turns to enter the canal.

Cranial Nerve V: The Trigeminal Nerve

The trigeminal nerve supplies sensation to the face through three major peripheral branches: the ophthalmic (V1), maxillary (V2), and mandibular (V3) nerves. V1 and V2 are purely sensory, whereas V3 also carries motor fibers to the muscles

of mastication. VI is also responsible for the corneal reflex. Traumatic injury to the branches of the trigeminal nerve is uncommon but may result from dental, surgical, or cranial trauma. Several cases of damage by supraglottic airway devices to the lingual nerve have been reported. This nerve, which is a branch of the mandibular division, is joined by the chorda tympani from cranial nerve VII and provides sensation to the anterior two-thirds of the tongue. Compression of this branch by the device results in temporary loss of sensation and taste (from the gustatory fibers of cranial nerve VII) in the anterior tongue, which, although potentially upsetting to the patient, generally resolves spontaneously within 6 to 9 weeks. The patient experiencing these symptoms postoperatively should be reassured regarding chance of recovery.

Cranial Nerve VII: The Facial Nerve

The facial nerve provides most of the motor innervation for the muscles of expression in the face. It also, via the nervus intermedius, relays afferent taste sensation from the anterior two-thirds of the tongue and carries sympathetic fibers to the lacrimal and salivary glands. Depending on the location of the injury, motor, autonomic, and gustatory deficits may be seen. Lesions of the intracranial portion of the nerve near the origin or close to the geniculate ganglion by the internal acoustic meatus may affect all three components, whereas those in the facial canal of the temporal bone between the geniculate ganglion and the origin of the chorda tympani near the stylomastoid foramen may spare lacrimation. Lesions occurring after the stylomastoid process in the extracranial portion of the nerve result primarily in motor deficits. Symptoms may be mild to severe depending on the severity of injury.

Injury to the facial nerve may present as complete paralysis of the facial muscles, with flattening of the facial folds around the nose, lips, and forehead; widening of palpebral fissures; and incomplete closure of the eyelid on the affected side, which can result in corneal scarring from desiccation, particularly if the injury also affects lacrimation. Decreased salivation and loss of taste in the anterior two-thirds of the tongue may also be present if the chorda tympani is affected. Less commonly, patients with seventh nerve injuries may experience sensitivity to loud sounds, or hyperacusis, as the facial nerve supplies motor input to the stapedius muscle, which has a dampening effect on the tympanic membrane. During regeneration, *synkinesis* may develop, which is the movement of unrelated facial muscles during attempts at isolated muscle movements, such as lip twitch with blinking, if aberrant reinnervation occurs. Importantly, lesions of the peripheral facial nerve can be distinguished from central motor pathway lesions by assessing involvement of the forehead. Central lesions spare forehead motion due to bilateral representation in the central nervous system, whereas peripheral lesions do not.

Traumatic injury to the facial nerve may result from temporal bone fracture, penetrating injuries such as knife or gunshot wounds, iatrogenic injury during resection of acoustic neuromas and other cerebellopontine angle lesions, or in the neonate at the time of delivery by the application of forceps. The superficial peripheral branches are particularly vulnerable to injury. Studies suggest that approximately 7% to 10% of temporal bone fractures result in facial nerve dysfunction. Trauma to the temporal bone may result in both an initial direct injury to the nerve followed by a secondary ischemic injury because edema causes increased pressure in the fallopian canal containing the nerve. Decompressive surgery may be necessary to prevent progression of injury and should be undertaken as early as possible. Likewise, penetrating injuries most often result in nerve transection and early surgical exploration is desirable. Surgical approach is dependent on the location of the injury.

Cranial Nerve IX: The Glossopharyngeal Nerve

Trauma to cranial nerves IX, X, XI, and XII is most often iatrogenic. The glossopharyngeal nerve carries both sensory and motor fibers. The sensory fibers transmit information from the upper part of the pharynx and taste from the posterior one-third of the tongue. The motor component innervates the constrictor muscles of the pharynx and the stylopharyngeus as well as secretory glands in the pharyngeal mucosa. Traumatic injury to the nerve occurs most commonly with fractures through the jugular foramen where it exits the skull together with the vagus and accessory nerves. Lesions resulting from trauma are rarely isolated and occur most commonly with injuries of the X and XI cranial nerves. Clinically, glossopharyngeal dysfunction presents with diminished taste in the posterior one-third of the tongue and loss of gag reflex on the side of the lesion. The presence of dysphagia or dysarthria may signal concomitant injury to the vagus nerve because these symptoms are rarely present in isolated glossopharyngeal injuries.

Cranial Nerve X: The Vagus Nerve

The vagus nerve provides motor, sensory, and autonomic innervation to a wide variety of targets. Motor fibers originating in the nucleus ambiguous in the brainstem innervate the somatic muscles of the pharynx and larynx, which coordinate the initial phase of swallowing. Autonomic fibers from the dorsal motor nucleus provide innervation to the heart, lungs, esophagus, and stomach. Sensory fibers from the upper gastrointestinal tract and oropharynx travel within the vagus nerve to the spinal nucleus, and sensation from the thoracic and abdominal organs is transmitted to the tractus solitarius. Dysarthria and dysphagia may occur with injury, and the palate on the affected side will be low at rest. Deviation of the uvula toward the unaffected side with phonation may be observed as the unopposed contralateral muscles contract.

Individual branches of the vagus nerve may be injured during surgical intervention on the head and neck. Careful physical examination aids injury localization because clinical presentation varies with site of lesion. Injury to the pharyngeal branches of the vagus nerve will present with dysphagia, which may be mild or severe. The superior laryngeal nerve, which carries sensory fibers from the larynx and provides motor innervation to the cricothyroid muscle, will present with anesthesia of the larynx and paralysis of the cricothyroid muscle. Injury to the recurrent laryngeal nerve leads to vocal cord paralysis, resulting in hoarseness and dysphonia. The voice may sound breathy or harsh during speech production. Bilateral injury results in complete vocal cord paralysis, which can be distinguished by the presence of dyspnea, inspiratory stridor, and an inability to phonate, *aphonia*. Lesions of the pharyngeal and superior laryngeal nerves may also produce vocal abnormalities, resulting in a voice that is weak and easily fatigable.

Cranial Nerve XI: The Spinal Accessory Nerve

The spinal accessory nerve, unlike the other cranial nerves, originates from the C2, C3, and C4 in the upper cervical spinal cord. It enters the skull through the foramen magnum and then

travels back out through the jugular foramen with cranial nerves IX and X. Like the glossopharyngeal and vagus nerves, the spinal accessory nerve may be damaged by trauma that results in fracture through the jugular foramen. Iatrogenic injury has also been observed during lymph node biopsy, internal jugular central venous line placement, and carotid endarterectomy. In these instances, injury generally occurs extracranially as the nerve passes through the posterior triangle in the neck.

The spinal accessory nerve carries motor fibers to the sternocleidomastoid muscle and the upper portion of the trapezius. Lesions of this nerve result in atrophy of the upper trapezius, inability to shrug the affected shoulder, and impairment in rotation of head to the contralateral side. Winging of the scapula at rest, which is worsened by abduction, may be present. The scapular winging that results from upper trapezius weakness may be distinguished from that associated with long thoracic nerve injury and anterior serratus weakness by the position of the scapula at rest. When the anterior serratus is affected, winging will be minimal at rest and increase with force applied to the outstretched arm when held out in front of the body.

Cranial Nerve XII: The Hypoglossal Nerve

The hypoglossal nerve originates from the medulla and exits the skull through the hypoglossal foramen in the posterior fossa. It carries motor fibers to the muscles of the tongue and is particularly important for articulation. Injury to this nerve produces dysarthria and atrophy with deviation of the tongue on protrusion toward the side of the lesion due to the action of the unopposed contralateral muscles. Trauma to the hypoglossal nerve has been reported with many surgical interventions including carotid endarterectomy, endotracheal intubation, and supraglottic airway device usage. Cranial nerve XII compression during head turning has also been observed to result from medially oriented, elongated styloid processes with associated ossification of the stylohyoid ligament. During acute head trauma, hypoglossal nerve injury may be associated with fracture of the occipital condyle. Presence of a 12th nerve palsy after trauma should prompt a magnetic resonance imaging of the cervical spine to assess spinal stability. Urgent decompression may be necessary to prevent irreversible injury to the spinal cord.

UPPER EXTREMITY NERVE LESIONS

The peripheral nerves of the upper extremity are vulnerable to traumatic injury by compression and stretch, lacerating and penetrating wounds, fracture and dislocation of nearby bones and joints, and ischemic and iatrogenic insults of various etiologies. Trauma, resulting in injury, may be either acute or chronic. Carpal tunnel syndrome and cubital tunnel syndrome are two examples of chronic entrapment syndromes, in which the application of chronic traumatic compressive forces result in impaired nerve function. These and other common entrapment syndromes are discussed in detail in subsequent chapters. This section focuses on common acute upper extremity traumatic peripheral nerve injuries and their mechanisms.

Brachial Plexus Injuries

Injury to the brachial plexus, which supplies much of the motor, sensory, and vasomotor innervation of the upper limb and shoulder, can be severely disabling, particularly as traumatic injury to the brachial plexus tends to occur most frequently within the productive age groups. Recovery is often incomplete, resulting in lasting disability, which may negatively affect quality of life. The superficial location, large size, and position between two highly mobile structures (the neck and the arm) make the brachial plexus vulnerable to traumatic injury. Although brachial plexopathies are discussed in greater detail elsewhere in this book, it is important for the clinician to be aware of common traumatic mechanisms and presentations of brachial plexus injury (Table 49.4).

The brachial plexus, which travels from the spinal cord to the axilla, is derived from the nerve roots of C5-T1. It is progressively

TABLE 49.4 Brachial Plexus Injuries, Mechanisms, and Presentation

Injury Classification	Mechanism of Injury	Clinical Presentation
Supraclavicular: *roots, trunks*	High-velocity injuries (eg, MVAs)	Motor and sensory loss in associated myotomes and dermatomes
Infraclavicular: *trunks, terminal nerves*	Penetrating injuries	Terminal branch deficits

Upper: C5-C6	Closed traction (Shoulder is forcibly separated from head.)
	• Contact sports
	• Prolonged operational positioning with contralateral rotation of head or upper extremity abduction greater than 90°
	• Excessive traction to plexus during delivery
		Erb palsy
		• Weakness/paralysis of deltoid, biceps, brachioradialis, pectoralis major, supraspinatus, infraspinatus, subscapularis, teres major
		• Loss of biceps reflex
		• Hypesthesia in lateral arm and forearm
		• "Waiter's tip" position:
		  • Internal rotation of arm
		  • Extension and pronation of forearm
		  • Flexion of wrist and fingers

Lower: C8-T1	Thoracic surgery requiring median sternotomy Cervical rib and band syndrome Obstetrical trauma Pancoast tumor	Klumpke palsy • Isolated hand paralysis • Ipsilateral Horner syndrome • Hypesthesia in medial arm and forearm and ulnar side of hand • Atrophy of intrinsic hand muscles • Loss of triceps reflex

Abbreviation: MVA, motor vehicle accident.

divided into five roots, three trunks (upper, middle, lower), six divisions (three anterior, three posterior), three cords (lateral, posterior, and medial), and several terminal branches, which provide motor, sensory, and sympathetic innervation to the upper limb. C5 and C6 contain the largest number of motor fibers, whereas C7 and T1 contain the least. C7 contains the largest amount of sensory fibers followed in descending order by C6, C8, T1, and C5. These relative sensory and motor distributions have implications for both injury presentation and chance of spontaneous functional recovery because nerves with greater proportion of either sensory or motor fibers have a greater likelihood of having regenerating axons make appropriate end-organ connections, as compared to mixed nerves.

Injury to the plexus occurs commonly with stretch from extreme positioning associated with falls, direct lacerating or penetrating trauma, dislocation of the shoulder, traction during birth, and stretch or compression during surgical positioning. Injury may be classified as *supraclavicular* (affecting roots and trunks), *retroclavicular* (divisions), or *infraclavicular* (trunks and terminal nerves), with the deficit pattern reflecting the site of injury. Supraclavicular lesions result in motor and sensory loss in myotomal and dermatomal distributions associated with the affected roots, whereas infraclavicular injuries tend to have deficits limited to the territories of the terminal branches. Infraclavicular injuries are more commonly seen with penetrating injuries, whereas high-velocity injuries, as occur with motor vehicle accidents, are more likely to result in closed traction supraclavicular injury patterns.

Additionally, injuries may be classified as *upper* (C5-C6), *lower* (C8-T1), or *panplexal* (C5-T1), with implications for both presentation and prognosis. The presence of Horner syndrome or involvement of proximal branches such as the dorsal scapular, which provides motor innervation to the rhomboids, or latissimus dorsi dysfunction due to long thoracic nerve injury, indicates a proximal injury and carries a poorer prognosis. Dysautonomic features, such as vasomotor abnormalities or skin changes, may be observed in the affected limb. Severe pain in an anesthetic limb may be suggestive of root avulsion, in which the nerve roots are torn from their attachment to the spinal cord by the force of the injury. Avulsion generally requires a different surgical approach than more distal nerve injuries and may carry a worse prognosis. In acute trauma, the position of the arm at time of impact, as well as the associated injuries, may provide clues to the clinician about possible plexus injuries.

The upper plexus is the most common site of injury. Injury to this region results from closed traction, which occurs when the shoulder is forcibly separated from the head. This injury pattern is common in contact sports as well as postoperatively as a result of prolonged positioning with contralateral rotation of the head or upper extremity abduction greater than 90°. It may also result from the application of excessive traction to the plexus during delivery and is referred to as *Erb palsy* (C5-C6) or *Erb palsy plus* (C5-C7), depending on the roots involved. Weakness or paralysis of the deltoid, biceps, brachioradialis, pectoralis major, supraspinatus, infraspinatus, subscapularis, and teres major results in the classic "waiter's tip" position, with internal rotation of the arm, extension and pronation of the forearm, and flexion of the wrists and fingers. The biceps reflex is absent and sensory loss incomplete, with hypesthesia on the outer surface of the arm and forearm. Contracture may result if passive range-of-motion exercises are not undertaken early. Prognosis for upper plexus injuries associated with birth trauma is generally very good, with 90% chance of spontaneous recovery reported most often in the literature, although controversy remains regarding the optimal timing of surgical intervention in these patients. Generally, the watchful waiting period of 3 to 6 months in adults with closed nerve injuries may be extended to 9 or more months in children, depending on the clinical circumstances.

Traumatic lower plexopathies, affecting C8-T1 nerve roots, are less common than upper plexus injuries but have been associated with thoracic surgery requiring median sternotomy, cervical rib and band syndrome, obstetrical trauma, and the presence of a Pancoast tumor by compression or direct tumor invasion. The resulting syndrome is referred to as *Klumpke palsy*. It presents with isolated hand paralysis and ipsilateral Horner syndrome. This clinical presentation mimics that of a combined median and ulnar lesion. Sensory loss is observed on the medial arm and forearm and the ulnar side of the hand. Atrophy of the intrinsic hand muscles occurs. The anatomic particularities of the C8 and T1 nerve roots make the lower plexus more susceptible to avulsion than the upper and middle plexus. The greater vulnerability to avulsion results in a poorer prognosis for lower plexus injuries.

Isolated middle plexus injury, affecting nerve root C7 or the middle trunk, is the least common form of traumatic brachial plexopathy. These lesions cause paralysis in a primarily radial distribution with sparing of the brachioradialis. Due to extensive dual innervation, sensory loss is minimal and may be limited hypesthesia over the dorsal surface of the hand and forearm.

A complete lesion of the brachial plexus results in a flail arm with or without ipsilateral Horner syndrome. Complete plexus injuries carry the worst prognosis and extensive surgical intervention may be required to restore function and alleviate pain.

Proximal Nerve Injuries

The *long thoracic nerve* is a purely motor nerve that arises from the ventral rami of C5-C7. It provides motor innervation to the serratus anterior muscle, which stabilizes, protracts, and upwardly rotates the scapula to abduct the arm over the head. Weakness or paralysis of this nerve results in winging of the scapula, which is particularly notable during abduction and forward flexion. Very little winging is observed at rest, which distinguishes long thoracic palsy from injury to the spinal accessory nerve. Abduction between 90° and 180° may be limited.

Injury to this nerve is most commonly seen in the context of more profound brachial plexus injuries. Iatrogenic injury has been associated with first rib resection and radical mastectomy. Isolated long thoracic injuries in the absence of a clear-cut mechanism are rare, and Parsonage-Turner syndrome should be considered as an alternative diagnosis in these cases.

The *suprascapular nerve* branches from the upper trunk and is derived of fibers mostly from C5. It provides motor innervation to the supraspinatus and the infraspinatus muscles as well as sensory and sympathetic innervation to two-thirds of the shoulder capsule, the glenohumeral, and the acromioclavicular joints. Weakness of the supraspinatus muscle results in difficulty in initiating shoulder abduction, particularly through the first 15° to 30°, after which the deltoid takes over. The infraspinatus externally rotates the shoulder, and weakness may be observed with external rotation as a result of suprascapular nerve injury. Isolated injury is rare with shoulder trauma, although

chronic trauma from entrapment by the suprascapular ligament has been reported. Compression by tumors and ganglion cysts may also occur.

Median Nerve

The median nerve derives from the C6-T1 nerve roots. In the forearm, it provides motor innervation to the pronator teres, the flexor carpi radialis, palmaris longus, and flexor digitorum superficialis muscles before branching into the purely motor anterior interosseous nerve and the main branch. The main branch passes through the carpal tunnel and then gives off the recurrent motor branch to the abductor pollicis brevis and the opponens brevis. It terminates in the palm where it supplies innervation to lumbricals I and II. The median nerve is therefore involved with pronation of the forearm, wrist flexion, thumb, index and middle finger flexion, and opposition of the thumb.

Additionally, the median nerve provides sensation to the radial palm, ventral thumb, index, middle fingers, and the radial half of the ring finger. The dorsal surfaces of the distal phalanx of the thumb, along with the terminal phalanges of the index and middle fingers, are also supplied by the median nerve.

Injury to the median nerve may occur at multiple points along its course as a result of trauma. Median nerve palsy has been associated with stabbing injuries to the brachial plexus, crush injury from prolonged crutch or tourniquet usage, fracture of the distal humerus, anterior shoulder dislocation, and Colles fracture of the wrist, although chronic trauma due to entrapment is the most common median nerve injury observed clinically. The nerve may become entrapped within the carpal tunnel or between the heads of the pronator teres in the forearm. Chronic entrapment within the carpal tunnel results in pain and sensory loss in the distal median distribution with wasting and weakness of the thenar muscles and lumbricals I and II. Direct traumatic injury to the median nerve has also been reported secondary to poorly placed steroid injections for treatment of carpal tunnel syndrome. Histologic examination in several cases revealed the presence of white crystals with the median nerve sheath suggesting that aberrant injection directly into the nerve was the likely mechanism of injury. Carpal tunnel syndrome is discussed more thoroughly in subsequent chapters.

Radial Nerve

The radial nerve arises from the posterior cord and contains elements from C5 to T1 nerve roots. It is composed of primarily motor fibers and provides innervation to the wrist, forearm, and finger extensors. It passes through the axilla to supply the triceps and then winds around the posterior humerus, descending in the spiral groove. The nerve innervates the brachioradialis and extensor carpi radialis longus muscles before branching into the superficial radial nerve, which carries sensory information from the dorsoradial aspect of the distal forearm and the dorsal surface of the hand and the posterior interosseous nerve, which supplies motor innervation to the remaining forearm, wrist, and finger extensors as well as the supinator.

The clinical presentation of traumatic injury to the radial nerve will vary with the level at which the injury occurs. Several common injury mechanisms have been identified that are associated with lesions at various levels. Injury to the nerve in the axilla, resulting from the use of crutches that are too long, causes extensor weakness and numbness in the radial distribution described earlier. Midshaft humeral fracture or external compression, referred to commonly as *Saturday night palsy* when it occurs after a particularly heavy night's sleep on an extended arm, causes weakness of forearm and wrist extensors with wrist drop and weakness of finger extensors. Elbow extension is preserved.

Iatrogenic trauma to the radial nerve has also been reported in the literature to have occurred with peripheral venous cannulation and arterial monitoring at the wrist, blood pressure cuffs at the midhumeral shaft, and rarely, with vaccine administration in the upper arm. Prognosis is generally good due to the predominant motor component of the radial nerve limiting motor/sensory cross-reinnervation and synergy between radial nerve–innervated muscles.

Ulnar Nerve

The ulnar nerve is a terminal branch of the medial cord of the plexus and contains fibers from C8 to T1 nerve roots. It descends between the biceps and triceps before moving posteriorly to pass behind the medial epicondyle and through the cubital tunnel to the forearm. It provides motor fibers to the flexor carpi ulnaris and flexor digitorum profundus II before passing through Guyon canal into the hand. The ulnar nerve terminates as a superficial sensory branch, which supplies the palmar and dorsal sides of the ulnar part of the hand and the palmar and dorsal surfaces of the little finger and the medial half of the ring finger. A deep motor branch supplies the abductor, opponens, and flexor digiti minimi medially and the adductor pollicis and the medial half of the flexor pollicis brevis laterally. It is responsible for many of the fine motor manipulations of the hand, and injury can be quite disabling.

The superficial course of the ulnar nerve behind the medial epicondyle makes this nerve vulnerable to injury by external compression. Ulnar nerve palsy is one of the most commonly reported postoperative peripheral nerve complications and may result from poor positioning, from insufficient padding around the elbow, or from external pressure by surgical instruments and personnel. Entrapment of the ulnar nerve may also occur at the elbow in the ulnar groove, distal to the elbow as it traverses the cubital tunnel, or within Guyon canal at the wrist. Several cases of ulnar nerve palsy at the wrist have been reported to result from ganglion cysts within Guyon canal, leading to weakness and atrophy of the intrinsic muscles of the hand. Injury to the ulnar nerve may also be seen with articular fractures of the distal humerus. Prolonged denervation may result in clawing of the little and ring finger, and atrophy of hypothenar and interosseous muscles.

The likelihood of functional recovery after traumatic injury is lower for the ulnar nerve than for either the median or the radial nerve. This inequity is attributed to the ulnar nerve's innervation of muscles responsible for fine movement in the hand, which require greater specificity in reinnervation to regain useful function.

Axillary Nerve

The axillary nerve arises as a terminal branch of the posterior cord with fibers originating from C5 to C6 nerve roots. The axillary nerve crosses anterior to the subscapularis before entering the quadrilateral space and dividing into two main trunks. The posterior branch supplies motor innervation to the teres minor

and posterior deltoid before terminating as the superior lateral brachial cutaneous nerve, whereas the anterior branch travels within the deltoid muscle providing motor innervation to the middle and anterior deltoid muscle.

Traumatic injury to the nerve is associated with glenohumeral dislocation, proximal humeral fracture, and direct blow to the deltoid muscle, as can occur during sports events. Compression can also occur within the quadrilateral space, resulting in deltoid muscle weakness and diffuse pain over the posterior shoulder. Compression is thought to be secondary to the development of abnormal fibrous bands and hypertrophy of the muscles forming the boundaries of the anatomic space. The axillary nerve is vulnerable to iatrogenic injury during surgery involving the shoulder and glenohumeral joint, including shoulder arthroscopy during portal placement. Clinically, injury to the axillary nerve may present with weakness of shoulder abduction and paresthesia over the lateral arm. Prognosis for axillary nerve injury is generally good, although it varies with injury mechanism and severity.

LOWER EXTREMITY NERVE LESIONS

Lumbosacral Plexus

The nerve supply to the pelvis and lower limbs originates from the lumbosacral plexus. Functionally and anatomically, the lumbosacral plexus can be divided into two major divisions, the lumbar and sacral plexuses (Table 49.5).

The lumbar plexus is formed within the psoas major muscle and is derived from the nerve roots of L2-L4. The lumbar plexus gives rise to the *femoral nerve*, which passes along the lateral border of the psoas major, under the inguinal ligament, to the anterior leg where it supplies motor innervation to the

TABLE 49.5 Lower Extremity Injuries, Mechanisms, and Presentation

Nerve	Mechanism of Injury	Clinical Presentation
Obturator	Compression from expanding pelvic masses (hematomas, tumors, abscesses) Labor	Abnormal gait due to adductor weakness Impaired internal/external rotation of thigh
Iliohypogastric/ Ilioinguinal	Iatrogenic complications of surgery • Aberrant suture/staple placement • Development of neuroma • Entrapment in fibrous adhesions	Anesthesia/paresthesia over a small strip of skin Pain
Lateral femoral cutaneous	Compression of anterior branch due to the following: • Tight-fitting belt/pants • Lumbar hyperlordosis from pregnancy • Prolonged maintenance of lithotomy position during surgery • Extreme hip flexion during vaginal delivery	Meralgia paresthetica • Dysesthesia and hypesthesia along lateral thigh
Femoral	Compression within pelvis (tumors, abscesses, enlarged lymph nodes) Spontaneous hematoma within iliacus or retroperitoneal space	Weakness of iliopsoas Paralysis of quadriceps femoris Hypesthesia over anteromedial leg (saphenous nerve distribution) Loss of patellar reflex Flexed, abducted, externally rotated leg Gait abnormality (especially walking on an incline)
Sciatic	In the buttocks: • Injection injury • Hip fracture/dislocation • Hip arthroplasty • Fall-related contusion • Gunshot wounds • Laceration • Compression from prolonged immobilization In thigh: • Gunshot wounds • Stretch injury associated with femoral shaft fracture • Laceration in posterior thigh In all locations, injury to common peroneal division is more common than injury of tibial division.	Weakness of knee flexion Paralysis of all movements of ankles and toes Loss of ankle reflex Foot drop on affected side Circular swinging motion of hip during leg advancement to compensate for loss of ankle dorsiflexion Hypesthesia over outer leg, shin, instep, dorsal surface of toes Sciatica (suggests compression at level of L5-S1 roots)
Common peroneal	Compression from prolonged leg crossing, squatting, or lateral decubitus position	Foot drop Weakness in ankle eversion Inability to extend toes Hypesthesia over outer leg, shin, instep, dorsal surface of toes
Tibial	Contusion with fracture, laceration, and gunshot wounds Tarsal tunnel syndrome	Paralysis of plantarflexion, inversion of foot, and flexion and abduction of toes Hypesthesia over plantar foot Loss of plantar reflex Burning/paresthesia/anesthesia over tarsal tunnel behind medial malleolus with radiation to plantar foot, heel, and arch

pectineus, sartorius, rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis muscles. The femoral nerve then terminates as the saphenous nerve, providing sensation to the medial lower leg.

The *obturator nerve* also arises from the anterior branches of L2, L3, and L4. It passes through the obturator canal in the pelvis and gives off anterior branches that supply the adductors. It also may provide sensation to the inner thigh and knee, although cutaneous innervation in this area is highly variable.

A number of smaller sensory nerves also arise from the lumbar plexus. These nerves include the *iliohypogastric*, the *ilioinguinal*, the *genitofemoral*, and the *lateral femoral cutaneous nerves*. Lesions of these nerves are discussed individually in the following text, but traumatic injury is most often iatrogenic or anatomic, and rarely the result of acute trauma.

The sacral plexus is formed from the nerve roots of L5, S1, and S2 with variable contribution from L4. The sacral plexus supplies motor innervation to the gluteus minimus, gluteus medius, and tensor fascia lata via the *superior gluteal nerve*, which contains fibers from L4 to S1, whereas the *inferior gluteal nerve*, derived from L5 to S1, supplies the gluteus maximus.

The *sciatic nerve* forms from the posterior divisions of L4-S1. It exits the pelvis through the greater sciatic foramen and through the piriformis muscle, which can act as a site of compression when hypertrophied. The sciatic nerve travels down the posterior leg as two anatomically approximated but functionally distinct components: the lateral peroneal portion and the medial tibial portion. In the posterior thigh, the lateral peroneal portion of the sciatic nerve provides motor innervation to the short head of the biceps femoris, whereas the medial tibial division supplies the long head of the biceps femoris, the semitendinosus, and the semimembranosus. The lateral position of the peroneal portion increases its vulnerability to injury, particularly from penetrating and concussive forces. At the level of the posterior knee, the sciatic nerve divides into the common peroneal and tibial nerves.

Traumatic injury to the lumbosacral plexus is uncommon, although injury has been observed to occur secondary to gynecologic surgery and normal labor due to compression by fetal presenting part or instrumentation used in vaginal delivery. Hematoma, abscess, and tumor may all present with lumbosacral plexopathy. Clinical presentation varies with the site and severity of injury, although damage to the plexus may be distinguished from more peripheral injury if dysfunction of the anal sphincter is present.

Obturator Nerve

Traumatic injury of the obturator nerve is uncommon; compression may result from expanding pelvic masses such as hematomas, tumors, abscesses, or from compression by the presenting part of the fetus during labor. Clinically, injury to the obturator nerve manifests as abnormal gait due to adductor weakness. Internal and external rotation of the thigh may also be affected.

Iliohypogastric Nerve

The iliohypogastric nerve is derived from the upper portion of the lumbar plexus. It provides sensation to the upper buttocks and the lower abdomen as well as supplying some motor innervation to the internal oblique and transversus abdominis muscle. Traumatic injury to this nerve is most commonly reported as an iatrogenic complication of surgery. Aberrant suture or staple placement, development of painful neuroma, or entrapment of the nerve in fibrous adhesions can cause anesthesia, paresthesias, and pain that is refractory to most conventional pain management strategies. Entrapment in mesh used for hernia repair has also been reported. In cases of nerve injury uncomplicated by pain, lesion to this nerve may produce minimal deficits with anesthesia over a small strip of skin as the primary manifestation.

Ilioinguinal Nerve

The ilioinguinal nerve provides sensation to the pubic region, the upper inner thigh, and the external genitalia. Injury to the ilioinguinal nerve often accompanies injury to the iliohypogastric nerves and is associated with similar traumatic mechanisms.

Genitofemoral Nerve

The genitofemoral nerve is a sensory nerve that derives from the L2 nerve root. It provides sensation to the scrotum and a portion of the inner thigh. Traumatic injury of this nerve is rare.

Lateral Femoral Cutaneous Nerve

The lateral femoral cutaneous nerve is derived from nerve fibers between L2 and L3. This sensory nerve travels beneath the fascia of the iliacus and emerges at the anterior superior iliac spine. It divides into two branches: a posterior branch, which provides sensation to the external buttock, and an anterior branch, which provides sensation to the outer lateral thigh. A syndrome called *meralgia paresthetica*, which consists of dysesthesia and sensory loss along the lateral thigh, occurs with compression of the anterior branch. Compression may result as a consequence of tight-fitting belts and pants, lumbar hyperlordosis resulting from pregnancy, prolonged maintenance of the lithotomy position during surgery, or extreme hip flexion during vaginal delivery. Hypertrophy of the iliopsoas, as can occur with dancers who repeatedly maintain the leg in greater than 90° of flexion, has also been reported as a cause of lateral cutaneous femoral neuropathy.

Femoral Nerve

Traumatic injury to the femoral nerve is less common than injury to the sciatic, common peroneal, or tibial nerves, although injury may result from femur and pubic ramus fractures. More commonly, injury to the femoral nerve is derived from compression within the pelvis by tumor, abscesses, and other space-occupying lesions such as enlarged lymph nodes. Spontaneous hematoma within the iliacus or retroperitoneal space, associated classically with hemophilia and more recently with the use of anticoagulation medication, has also been described in the literature as a cause of femoral neuropathy. In hemophiliacs, it has been shown that bleeding into the iliacus muscle, which occupies a nondistensible space between the pelvic bone and the iliac fascia, raises the pressure within the compartment, compressing the femoral nerve as it travels between the iliacus and psoas muscles. A second mechanism has also been proposed based on more recent anatomic studies, which suggests that blood within the iliac fascia traps the femoral nerve at the point at which it

passes beneath the inguinal ligament. In this model, hemorrhagic dissection down to the level of the inguinal ligament is necessary for compression to occur and may explain why femoral neuropathy generally presents in isolation.

Injury to the femoral nerve results in weakness of the iliopsoas, paralysis of the quadriceps femoris, and hypesthesia over the anteromedial leg in the distribution of the saphenous nerve. Patellar reflex is lost and the leg is often held in flexed, abducted, and externally rotated position. Severe abnormalities in gait may be observed, particularly when attempting to walk on an incline or upstairs because both hip flexion and knee extension are affected.

Sciatic Nerve

Lesions of the sciatic nerve comprise the largest subset of lower extremity traumatic injuries. At the level of the buttocks, injection injury is the most common cause of traumatic nerve lesion with hip fracture/dislocation; hip arthroplasty; fall-related contusion; gunshot wounds; laceration, such as from a boat propeller; and compression from prolonged immobilization following in descending order. In the thigh, gunshot wounds, followed by stretch injury associated with femoral shaft fracture, and laceration in the posterior thigh were the most common mechanisms of traumatic injury. In all locations, injury to the common peroneal division of the sciatic nerve occurs more frequently than injury of the tibial division. This is hypothesized to be the result of the lateral position of the peroneal division.

Complete lesion of the sciatic nerve is rare. Clinically, it presents as weakness of knee flexion as well as complete paralysis of all movements of the ankles and toes. Ankle reflex is lost and foot drop is observed on the affected side. Also, gait is characterized by a circular swinging motion of the hip during leg advancement because patients attempt to compensate for the loss of ankle dorsiflexion. Sensation is altered on the outer surface of the lower leg, over the toes, and on the instep and sole of the foot. *Sciatica*, or pain extending from the low back to the toes following the course of the nerves that is associated with foot drop and weakness in ankle eversion, suggests compression at the level of the L5-S1 nerve roots and should warrant imaging evaluation of the lumbar spine.

Common Peroneal Nerve

The common peroneal nerve is particularly vulnerable to traumatic injury. Its anatomic course around the fibular head makes it susceptible to stretch, contusion, and compression forces around the knee as well as to laceration resulting from fibular fracture. Compressive trauma may occur with leg crossing, squatting, or prolonged lateral decubitus position with insufficient padding while sleeping, unconscious, or anesthetized. Injury to the common peroneal nerve results in footdrop and weakness in ankle eversion. Patients may be unable to extend the toes. Depending on the level of injury, sensory loss may occur over the outer leg, shin, instep, and dorsal surface of the four small toes.

Injuries to the common peroneal nerve carry a worse prognosis than do injuries to other nerves of the lower leg. This is thought to be due to a number of factors including the distance from target end organs, the mixed nature of the nerve, the risk for more severe injury associated with the nerve's lateral location, and the characteristics of the target muscles, which require coordinated input for effective contraction. Distal injuries tend to have a better chance of recovery than do their proximal counterparts.

Tibial Nerve

Injury to the tibial nerve occurs significantly less frequently than injury to the common peroneal, and it carries a much better prognosis. Contusion with fracture, laceration, and gunshot wounds are the most common mechanisms of traumatic injury. Because the tibial nerve provides motor innervation to the gastrocnemius and soleus, complete lesion of the nerve leads to paralysis of plantarflexion and inversion of the foot as well as flexion and abduction of the toes. Sensory loss occurs over the plantar aspect of the foot and plantar reflex is lost.

A syndrome of chronic trauma by entrapment, called *tarsal tunnel* syndrome, has also been described as occurring within the flexor retinaculum in proximity to the medial malleolus. This syndrome produces a variable pain over the tarsal tunnel behind the medial malleolus with radiation to the plantar aspect of the foot, heel, and arch, which may be described as burning, tingling, or numbness. Discomfort is often exacerbated by prolonged weight-bearing activity and may be present at night. Bifurcation of the tibial nerve into the medial and lateral plantar nerves proximal to the tunnel is thought to be an anatomically predisposing factor for the development of the syndrome.

Prognosis after tibial nerve injury is favorable compared to that of the common peroneal nerve. This is attributed to several factors intrinsic to the nerve including a greater connective tissue to fascicle ratio, with increased shock-absorbing capabilities; a singular fixation point, which provides more elasticity and protection from stretch; a better blood supply to minimize secondary ischemic damage; and closer proximity to end-organ targets. Additionally, functional recovery is aided by the size and biomechanical characteristics of the gastrocnemius and soleus muscles, which require relatively little innervation for contraction to be effective.

DIAGNOSIS

The initial diagnosis of traumatic nerve injury is clinical; it relies primarily on a thorough physical examination and the identification of a history that is suggestive of acute or chronic trauma. The mechanism of trauma, along with the presence of injuries to other structures, such as skeletal fractures or lacerations that are commonly associated with injury to peripheral nerves, may help focus the clinician's initial examination on those areas most likely to be effected, although a full cranial and peripheral nerve examination should be undertaken whenever possible. Evaluation may be complicated by injuries that require immediate lifesaving therapeutic intervention as well as by alterations in level of consciousness in a multi-injury trauma patient.

Once a peripheral nerve injury has been identified by clinical evaluation, additional information should be sought regarding pathophysiology and extent of the injury because these factors will influence the timing and type of treatment provided. Several laboratory and imaging tools are available to aid in classification, including electrodiagnostic studies, ultrasound,

magnetic resonance imaging, magnetic resonance neurography, and somatosensory-evoked potentials.

Electrodiagnostic Findings in Peripheral Nerve Injury

Electrodiagnostic evaluation, consisting primarily of electromyography (EMG) and nerve conduction studies, is critical for establishing the severity, location, and prognosis of peripheral nerve lesions. Properly timed examination seeks to answer four important questions: (1) localization of the injury, (2) pathophysiology, (3) severity of resultant dysfunction, and (4) progress of reinnervation and likelihood of spontaneous recovery. More detailed information regarding the administration and general characteristics of these tests is provided in other chapters. In this section, we focus on the electrophysiologic characteristics associated with each of Seddon's nerve injury types and their impact on surgical planning.

Neurapraxia

Neurapraxic lesions are characterized by focal conduction block at the site of the lesion with no loss of conduction in the distal segment. The injury, which is usually the result of direct compression or ischemia, results in focal demyelination with no associated axonal loss. On nerve conduction studies, this is reflected by maintenance of the compound muscle action potential (CMAP) and sensory nerve action potential (SNAP) on stimulation distal to the lesion site when recording from distal nerve targets. When stimulation is applied proximal to the lesion, CMAP recordings might show loss of amplitude, slowing of conduction velocity, and change in morphology. SNAP will demonstrate a similar pattern, although interpretation of SNAPs is somewhat more complicated because amplitude is also affected by distance between the stimulating and recording electrodes. Abnormalities are expected to resolve with remyelination, although some conduction slowing may persist permanently because remyelination results in shorter and thinner internodes than previously present, with slightly decreased conduction capability.

Needle EMG of neurapraxic lesions is characterized by loss of motor unit action potentials (MUAPs) that are under voluntary control and abnormal patterns of motor unit recruitment. In incomplete lesions in which some proportion of axons are blocked, rendering some motor units ineffective, remaining unaffected motor units must increase the rate of firing to generate the same amount of force. On EMG, this abnormal recruitment results in a decreased number of MUAPs of normal morphology, amplitude, and duration, firing rapidly. No MUAPs will be observed with complete neurapraxic lesions. Resolution of these findings will occur with remyelination.

Axonotmesis

In axonotmesis, unlike neurapraxia, injury to the nerve produces complete or partial axonal disruption, resulting in progressive degeneration of the distal stump. The time to completion of the degenerative process depends on the length of the distal stump, as well as on fiber composition, but is generally completed within 10 to 14 days. The time required to complete this process is reflected in the evolution of the electrodiagnostic picture, and studies carried out in the acute traumatic period will not adequately distinguish neurapraxic from axonotmetic and neurotmetic lesions.

Generally, on nerve conduction studies, upon completion of the degenerative process, CMAP and SNAP, distal to the injury, will show a decrease in amplitude that is proportional to the degree of axonal loss. Motor fibers degenerate more quickly, with completion experimentally determined to occur around 5 to 8 days, and complete loss of amplitude observed around 9 days. Sensory fibers require more time, and complete loss is generally observed at day 11. Comparison of CMAP amplitude in the injured limb may be made to that of the unaffected side to approximate the degree of axonal loss. Comparison of distal to proximal CMAP amplitude within the affected limb may estimate the amount of demyelination present.

Needle EMG provides a measure of end-organ denervation. Fibrillation potentials and sharp waves are markers of denervation resulting from axonal degeneration in complete lesions. Their appearance distinguishes neurapraxic lesions from axonotmesis and neurotmesis, although the timing of their appearance is dependent on the distance from the injury site. Proximal muscles may begin to show fibrillation potentials at 10 to 14 days, whereas distal muscles may require 3 to 4 weeks. Incomplete lesions will show firing patterns similar to that of neurapraxia.

As regeneration progresses, motor units will remodel. Surviving MUAPs will become increasingly complex and "nascent units" will develop. Nascent units are characteristically of small amplitude, polyphasic, and with a rapid firing rate. These early MUAPs will develop into fully reinnervated units, which exhibit large amplitude, increased duration, and polyphasia, indicating increased motor unit territory. Evidence of such reinnervation, from local sources, may appear as early as 3 weeks, indicating the possibility of spontaneous recovery, although generally axonal reinnervation requires 3 to 4 months before adequate assessment can be made. Serial examinations may be used to follow the progress of reinnervation. If no evidence of regeneration is found within 3 to 6 months, surgical exploration may be appropriate.

Neurotmesis

Neurotmetic lesions are by definition complete lesions, resulting from transection of all structural nerve elements. Initial electrodiagnostic studies will follow the same pattern of progressive degeneration as occurs in axonotmesis. Unlike axonotmesis, no evidence of reinnervation will be apparent on follow-up examinations because fully transected nerves are not capable of undergoing functional spontaneous regeneration. Surgical intervention with grafting or tension-free reapproximation is required.

Timing of Studies

Some debate exists regarding the optimal timing of electrodiagnostic evaluations. Conventional teaching is that initial evaluation should be performed no earlier than 3 weeks to allow for degeneration to be completed. Immediate evaluation, within 7 days of the injury, on the other hand, has been proposed as a potentially valuable tool both in lesion localization and to determine whether a lesion is complete or incomplete. Detection of conduction block precisely identifies the location of the injury, which may be particularly helpful in the setting of extensive or anatomically distorting trauma. Incomplete lesions

carry a better prognosis and are less likely to need early surgical intervention.

In general, the timing of studies should reflect the clinical setting and questions to be answered, with the following guidelines applicable: (1) Studies performed within 1 week provide information regarding completeness of lesion and location; (2) at 1 to 2 weeks, neurapraxia can be separated from axonotmesis and neurotmesis; (3) evaluation at 3 weeks provides the most information regarding lesion type and prognosis; and (4) by 3 to 4 months evidence of reinnervation should be present.

Role in Surgical Planning

EMG is also an important tool for surgical planning. In thinking about nerve repair and functional recovery, consideration must be given to the time required for regenerating axons to reach the target tissues and establish mature connections. This thought is particularly important for motor recovery because irreversible changes are observed to occur in muscle within 12 to 18 months, rendering innervation after that point ineffectual. Regeneration, after either grafting or direct anastomosis, occurs at a rate of approximately 1 inch per month. Surgery must be timed to allow for the appropriate period of regeneration to occur. EMG assists in this planning by monitoring the progression of reinnervation. By measuring the distance from the injury site to the most proximal muscle and calculating the time needed for reinnervation to occur based on regeneration rate, EMG evaluation can be planned to assess for spontaneous recovery within a timeframe that would still facilitate successful surgical intervention. Surgery may provide some benefit when performed outside the ideal window because sensory targets remain viable for up to 2 to 3 years and reestablishment of protective sensation may be achieved.

TREATMENT

The timing and technique of surgical intervention is dependent on the mechanism and characteristics of the nerve injury. Injuries may be classified as either open or closed, depending on the status of the associated cutaneous tissue (Figs. 49.1 and 49.2).

Closed peripheral nerve injuries occur most commonly as a result of stretching, contusion, or compression and are more likely to be in continuity. Transection is rare, and neurapraxic and axonotmetic injuries predominate. Lesions of this sort rarely require immediate surgical intervention and should be managed conservatively for a period of at least 3 months to allow for spontaneous recovery.

Open injuries, which result from lacerations, are more frequently associated with neurotmetic lesions and may require early surgery. In general, prognosis for functional recovery is better if spontaneous regeneration is able to occur. Therefore, open injuries with a nerve in continuity may be treated conservatively, with medical management, early mobilization and physical therapy, and serial electrodiagnostic studies to monitor progress. If no evidence of reinnervation is found within 3 months, surgical exploration may be appropriate. On the other hand, for open injuries with evidence of nerve transection, early surgical exploration is preferred. The timing and extent of the surgery will differ according to the mechanism of injury.

Sharp injury to a nerve, as is seen most commonly with knife or scalpel wounds, results in clean transection with minimal trauma to adjacent nerve tissue and no inflammation. Sharp injuries should be repaired promptly, ideally within the first 3 days after injury, and are usually able to be directly reapproximated with tension-free suture. Prognosis is generally good in these cases.

Blunt transections that are often associated with boat propeller accidents have significant inflammation and damage to

FIGURE 49.1 Initial evaluation of open nerve injury.

FIGURE 49.2 Closed nerve injury management. Abbreviation: EMG, electromyography.

surrounding tissues. Inflammatory changes in the blunt ends continue to evolve over a period of 3 weeks, and surgical repair should be delayed. Ongoing inflammation can disrupt the repair. Direct reapproximation is less likely to be successfully performed because the contused areas must be trimmed back to the point of healthy tissue, lengthening the gap. Nerve grafting may be necessary. Prognosis is poorer after grafting than direct neurorrhaphy, but good functional recovery may still be achieved.

Nerve injuries sustained as a result of gunshot wounds require special consideration. Most lesions caused by gunshot wounds are the result of indirect heat and shock waves generated by the bullet, rather than transection. As continuity is usually preserved, spontaneous recovery may be achieved. Furthermore, damage to surrounding tissues may limit the success of early repairs. Therefore, surgical exploration and repair should be delayed for 3 to 4 months postinjury.

Indications for Early Operative Management

Early operative management may be indicated in certain settings. As discussed earlier, sharp transections, in which transected ends are not significantly contused, benefit from surgery performed within 3 days. Progressive nerve deficit suggests the presence of associated vascular injury or abnormality. Evidence of an expanding hematoma, pseudoaneurysm, or other compressive lesion should prompt early surgical intervention to alleviate compression.

TABLE 49.6 Surgical Repair Options

Surgical Technique	Description	Indications
External neurolysis	Dissection and mobilization of nerve from surrounding tissue	Positive response to electric stimulus—external neurolysis may be sufficient Negative response to electric stimulus—resection and repair may be warranted
Internal neurolysis	Dissection and removal of individual nerve fascicles for evaluation and scar tissue removal	Incomplete lesions associated with pain refractory to conventional medical therapy Performed as part of split repair
Split repair	Testing individual fascicles, preserving conducting fascicles, and resecting/repairing nonconducting fascicles with end-to-end neurorrhaphy or with grafts	Conductive heterogeneity around circumference of a nerve as indicated by electrophysiologic examination
End-to-end neurorrhaphy	Reapproximation and suturing together of transected nerve ends	Repairing sharp transections
Graft repair	Sural, antebrachial cutaneous, or superficial sensory radial nerve is harvested from patient. Damaged nerve tissue is removed from lesion site proximally and distally until normal fascicular structure is identified. Groups of fascicles are separated and small-caliber donor nerve graphs are sutured to healthy nerve tissue.	Nerve gaps that are too long to be repaired via end-to-end neurorrhaphy (blunt transections)
Nerve transfer (neurotization, nerve crossing, heterotopic nerve suture)	Proximal end of recipient nerve is sutured to an epineural window of the intact donor nerve. For example: • Transfer of ulnar nerve to motor branch of biceps or intercostal nerves to musculocutaneous nerve to restore elbow flexion • Transfer of spinal accessory nerve to suprascapular nerve to restore shoulder abduction	Avulsive injuries of brachial plexus
Tendon transfer	Transfer of entire functioning muscle, with its innervation, to replace actions of one that is paralyzed	Final option for restoring function and stability for patients presenting late for treatment

Surgical Techniques

The goal of surgical repair is to restore functional connectivity across the site of lesion and to alleviate neural pain. This may be accomplished by the removal of scar tissue, reapproximation and direct suturing of transected nerve ends, or through the interposition of graft material. The type and extent of surgical intervention is dependent on lesion characteristics (Table 49.6).

Neurolysis

The term *neurolysis* refers to the exposure of a peripheral nerve and dissection free of surrounding tissues. External or internal neurolysis may be performed.

External neurolysis is the first step of all surgical peripheral nerve interventions. During this step, the nerve is freed from surrounding tissue and mobilized (Fig. 49.3). Thickened and scarred areas of the endoneurium are removed as the surgeon progresses from normal to abnormal tissue, distal and proximal to the lesion. Careful dissection seeks to minimize disruption to vasculature that could slow healing or cause secondary injury.

For lesions in continuity, upon completion of external neurolysis, intraoperative stimulation and electrophysiologic recording is employed to assess functional connectivity. An electric stimulus is applied proximal to the lesion, and response is recorded distally (Fig. 49.4). If a measurable response is present in the distal segment, external neurolysis may be sufficient to relieve pain and support healing. If no response is noted, resection and repair may be warranted. Performing external neurolysis prior to intraoperative electrophysiologic evaluation allows more accurate placement of electrodes.

Internal neurolysis refers to the dissection and mobilization of individual nerve fascicles for evaluation and scar tissue removal. It is indicated for use with incomplete lesions that are associated with pain refractory to conventional medical therapy. Removal of scar tissue from around individual fascicles may help alleviate neuropathic pain, but dissection within the nerve

FIGURE 49.3 Intraoperative photo demonstrating a sural nerve injury that occurred during an Achilles tendon repair. External neurolysis across the injured segment reveals a traumatic neuroma marked by the *black bracket*. The nerve is in continuity.

FIGURE 49.4 Intraoperative photo demonstrating a sural nerve neuroma-in-continuity marked with the *black bracket*. Intraoperative nerve action potential recording using the hook electrodes reveal no conduction across the injured segment. Therefore, the neuroma is excised, and a conduit repair is performed.

sheath has the potential to damage regenerating axons. Internal neurolysis is also performed as part of a split repair, described in the following text. Internal neurolysis is also used to relieve compression of the nerve from intrinsic scarring, as found in hourglass constrictions.

Split Repair

Split repair is an operative technique that is used when electrophysiologic examination reveals conductive heterogeneity around the circumference of a nerve. After internal neurolysis is completed, individual fascicles (or groups of fascicles) can be tested and preserved if conductance across the lesion is achieved. Those fascicles that do not conduct will undergo resection and repair with either direct end-to-end neurorrhaphy or with grafts. The benefit of the split repair technique is that it allows uninjured fascicles to undergo spontaneous regeneration, which generally is more successful than either direct suturing or graft interposition.

End-to-End Neurorrhaphy

End-to-end neurorrhaphy refers to the reapproximation and suturing together of transected nerve ends. It is commonly used to repair sharp transections and generally carries a better prognosis than grafting. The use of this technique is limited by the size of the gap created after resection of injured tissue. Excessive tension at the suture line can increase scar formation and impede functional recovery. External neurolysis and mobilization of the nerve stumps may help to decrease the gap length. Transposition of some nerves, such as the ulnar nerve at the elbow, may also provide more length. Groups of fascicles may be individually reapproximated and sutured to help minimize formation of neuroma and maximize chance of regeneration. Because the composition of fascicles changes every 1 to 2 mm, various techniques have been developed to try to match fascicles by predominant component, motor or sensory, to improve the chance of proper end-organ target reinnervation.

Graft Repair

For nerve gaps that are too long to be directly sutured without excessive tension, nerve graft repair is indicated. Longer gap lengths are commonly seen as a result of blunt transections, which damage tissue surrounding the lesion, and moderate to long complete lesions in continuity, which require resection. Although autografts are used most commonly today, cadaveric nerve grafts and specialized hollow tubes have also been used to restore continuity of the nerve.

For this procedure, the sural, antebrachial cutaneous, or superficial sensory radial nerve is harvested from the patient. Damaged nerve tissue is removed from the lesion site proximally and distally until normal fascicular structure is identified. Groups of fascicles are carefully separated and small-caliber donor nerve graphs are sutured to the healthy nerve tissue. The ends of the grafts are "fish-mouthed" or spread to increase the surface area. Good results can be achieved with this technique, although controversy exists regarding the maximum length for which grafts are successful. An inverse relationship has been observed between graft length and prognosis.

Nerve Transfer

Nerve transfer is an additional option for restoring function to an injured limb, particularly when the nerve lesion cannot be repaired by the techniques described earlier. This technique, which is also referred to as *neurotization*, is used most commonly to treat injuries of the brachial plexus. In this surgical technique, an uninjured nerve is used as a substitute for one that is no longer working. Transfers may be single or dual, in which either one or two nerve transfers are used to restore function. Nerves may be coapted end-to-end or end-to-side in which the proximal end of the recipient nerve is sutured to an epineural window in the intact, donor nerve. Generally, end-to-end direct neurorrhaphy is preferred.

The most commonly used procedure for restoration of elbow flexion was described by Oberlin and colleagues in 1994. During the Oberlin procedure, one or two fascicles from the ulnar nerve branch are transferred directly to the motor branch of the biceps. Intraoperative stimulation may be employed to identify fascicles of the ulnar nerve that innervate the flexor carpi ulnaris to minimize resulting deficit. Direct transfer of the ulnar fascicles to the biceps motor branch reduces sensory/motor cross-reinnervation by limiting aberrant motor reinnervation of the sensory territory of the lateral antebrachial cutaneous nerve. A second common procedure used to reestablish elbow flexion is transfer of a group of intercostal nerves to the musculocutaneous nerve. This transfer may be used when the Oberlin procedure is not available. Because the intercostal nerve is not a native elbow flexor, a period of retraining, which can extend from 12 to 24 months, may be necessary to restore function.

Similar procedures are used to restore shoulder abduction and external rotation, which are important for shoulder stability. The most commonly used procedure to restore shoulder abduction is the transfer of the spinal accessory nerve to the suprascapular nerve. In this procedure, distal fascicles of the spinal accessory nerve are directly sutured to the suprascapular nerve, which provides motor innervation to the supraspinatus. Superior branches of the spinal accessory nerve, which innervate the trapezius, are left intact to preserve function. An additional strategy to restore shoulder abduction is transfer of the triceps

branch of the radial nerve to the axillary nerve, which innervates the deltoid. Nerve branches of the long, medial, or lateral head of the triceps may be used. This procedure may be combined with spinal accessory transfer to maximize chance of functional recovery. In all cases, the choice of intervention derives from the needs and functional status of the individual patient.

Tendon Transfer

A final option for restoring some function and stability for patients who present for late treatment, when successful reinnervation is less likely, is tendon transfer. Tendon transfer consists of the transfer of an entire functioning muscle, with its innervation, to replace the actions of one that is paralyzed and thereby restore some motion across a joint. Tendon transfers are generally the last resort before fusion options are considered.

OUTCOMES

Functional restoration is dependent on both injury and patient-specific factors. Age, mechanism and type of injury, location, and timing of intervention all influence the final outcome. The interaction of these complex clinical characteristics makes prognostication difficult.

In general, neurapraxic lesions have the best prognosis with functional recovery apparent within weeks to a few months. Axonotmetic injuries recover more slowly, requiring several months for regeneration to occur. Neurotmetic lesions carry the worse prognosis with chance of recovery closely related to timing and type of surgical intervention. These lesions will not recover spontaneously. Sensory restoration can continue for a period of up to 3 years, whereas muscle targets are no longer viable after 12 to 18 months. Spontaneous recovery always carries a better prognosis than surgical reapproximation, and clinical recovery may be followed for up to 3 years.

Mild Cognitive Impairment 50

Lawrence S. Honig, Arash Salardini, William Charles Kreisl, and James M. Noble

KEY POINTS

1. Mild cognitive impairment (MCI) is a cognitive state that falls between normal aging and dementia.
2. MCI subtypes are defined by which cognitive domains are affected: amnestic MCI and nonamnestic MCI.
3. Individuals with MCI, particularly amnestic MCI, are at increased risk for progressing to dementia, most often Alzheimer disease.
4. The evaluation of MCI should proceed similarly to the evaluation of the patient with dementia.
5. Diagnostic testing in MCI consists of testing to exclude reversible causes of cognitive impairment and identify domains most affected.
6. Imaging and cerebrospinal fluid studies can be used to determine the likelihood that a patient with MCI will progress to Alzheimer disease or other neurodegenerative diseases.
7. There are no currently approved treatments for MCI.

INTRODUCTION

Cognitive complaints are common in the aging population. In many cases, history and examination reveal significant impairment in more than one cognitive domain and concomitant functional decline—and in these cases, the findings provide for a diagnosis of dementia (see Chapter 12). However, in many other cases, there may be involvement of just one cognitive domain and/or lack of any clear functional decline, and diagnosis of dementia may not be warranted. An "intermediate state," representing neither dementia proper nor normality, clearly exists in the gradually progressive transition from normal brain health to dementia. Over time, several terms were developed to categorize such a transitional state as a diagnostic entity, even if representative of an early stage of a degenerative brain disease. In the 20th century, a variety of nonspecific terms were invoked to describe this intermediate state, including *pure amnestic disorder*, *age-related memory impairment*, *age-associated memory impairment*, *questionable dementia*, *cognitive impairment no dementia*, and *prodromal dementia*. Originally, such terms were predicated on the idea that cognitive changes were perhaps to be expected as part of aging. With the increased understanding of the biologic underpinnings of cognitive disorders, this view became less tenable. Thus for individuals with impairment not meeting dementia criteria, the term *mild cognitive impairment* (MCI) was coined.

The original clinical definition of MCI was memory-based and required a subjective memory complaint, a documented objective deficit in memory, overall normal general cognitive function, and a lack of "significant" functional impairment precluding a diagnosis of dementia. This was codified by the American Academy of Neurology in 2001. The definition of MCI has been broadened to domains other than memory to reflect non–Alzheimer dementias (Table 50.1). These other types of MCI include single domain amnestic MCI, amnestic multidomain MCI, nonamnestic single domain MCI, and nonamnestic multidomain MCI (Table 50.2). Research approaches have further refined the continuum of MCI itself into earlier and later stages based on objective neuropsychological test performance, the earliest stage of which is termed *subjective cognitive decline* when identified by patient self-report. This chapter discusses MCI reflecting this spectrum of potential stages including subjective cognitive decline.

TABLE 50.1 Broad Definition of Mild Cognitive Impairment

Core Criteria	Examples
Subjective (self-reported or informant-reported) cognitive complaint	• Forgetfulness about events, appointments, or items of information • Forgetfulness regarding date or time • Misplacing or "losing" objects • Word-finding problems, such as "forgetting words" • Spatial disorientation, such as becoming lost
Objective evidence of cognitive dysfunction on testing	• Decreased performance on standardized testing of cognitive domains, including memory, language, visuospatial, attentional, or executive functions or skills[a]
Preservation of functional activities	• Essentially normal function in living activities[b]
Absence of diagnosis of dementia	• Diagnosis of dementia is exclusionary.[c]

[a]Various cutoffs have been used for the objective tests, including 1.5 standard deviations below age- and sex-adjusted norms on one or more tests within a particular cognitive domain.

[b]Functional preservation is the most problematic of the three core inclusionary features because function may depend on living situation and demands.

[c]Diagnosis of mild cognitive impairment and dementia are mutually exclusionary, but diagnosis of dementia is not independent from the criteria in the table.

TABLE 50.2 Classification of Types of Mild Cognitive Impairment (MCI)[a]

MCI Type	Domains Affected	Possible Prodromal Disease
Amnestic single domain	Memory alone	Alzheimer disease
Amnestic multidomain	Memory PLUS one or more other domain: language, attention, executive, or visuospatial dysfunction	Alzheimer disease, dementia with Lewy bodies
Nonamnestic single domain	Language, attention, executive, or visuospatial dysfunction	Frontotemporal dementia, Lewy body dementia (including dementia with Lewy bodies and Parkinson disease dementia), vascular dementia, posterior cortical atrophy, hydrocephalus
Nonamnestic multidomain	Memory not affected but more than one domain affected: language, attention, executive, or visuospatial dysfunction	Frontotemporal dementia, Lewy body dementia, vascular dementia, posterior cortical atrophy, hydrocephalus

[a]Different types of MCI, left-most column, may ultimately more likely represent, as shown in right-most column, prodromal states of different dementia disorders.

MCI has also been codified by the committees of the American Psychiatric Association in 2013. The formulation of the diagnostic criteria of *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, recognizes that for each dementing disorder, there must be a state in which the impairment does not reach the level of dementia. Thus, each dementing disorder is categorized as a "major neurocognitive disorder" or "minor neurocognitive disorder." For example, Alzheimer dementia is "major," whereas amnestic MCI is "minor." As noted in Chapter 12, the use of the terms "dementia" and "MCI" are likely to persist in both neurologic and lay parlances.

In summary, *MCI* is a diagnostic term referring to a cognitively impaired state of less extent or severity than a dementia. MCI is generally, but not always, an early symptomatic state of a neurodegenerative process. As reviewed in Chapters 12 and 51, Alzheimer disease is the most common underlying cause of dementia and is the likely outcome for most amnestic MCI patients. Biomarkers have allowed segmentation of the relatively slow neurodegenerative process of Alzheimer disease into different diagnostic phases. The National Institute on Aging and Alzheimer's Association workgroup in 2011 divided the Alzheimer neurodegenerative spectrum into three phases: "preclinical" disease in which persons are asymptomatic but have biomarker evidence of an early Alzheimer process, a "symptomatic predementia phase" synonymous with MCI, and then the actual symptomatic dementia phase of Alzheimer disease (**Table 50.3** and **Fig. 50.1**). Thus as best demonstrated in Alzheimer disease, the definition of MCI continues to evolve and increasingly incorporates biomarker-based evidence with clinical finding.

EPIDEMIOLOGY

Both incidence and prevalence of MCI increase with age. Prevalence estimates vary widely depending on the exact definition of MCI. Subjective memory or other cognitive complaints (eg, word finding) that are elicited upon interview are extremely common in the elderly, although they depend on the population examined; in the United States, there is a prevalence of about 80% in persons older than age 70 years. However, most such persons will not have MCI when using objective neuropsychological testing measures. A relatively small fraction of persons with subjective memory or cognitive complaints present for neurologic or medical attention. Many persons with MCI are unaware of their deficits and this impacts care-seeking behavior by themselves or care partners. Of those who do present for medical evaluation, yet do not have diagnosable dementia, a high proportion (as many as 85%) will indeed meet MCI criteria, and most of these will be amnestic MCI. Once identified, a large proportion of amnestic MCI cases ultimately develop dementia, mostly due to Alzheimer disease. This is to be expected given the relative prevalences of underlying dementia disorders (see **Table 50.2**).

MCI, defined as reasonably preserved function but combined subjective memory or cognitive change and objective memory or cognitive impairment (see **Table 50.1**), is not as common as subjective memory complaints. The prevalence and incidence rates of MCI depend on the population assessed, including age, education, and cultural milieu, and the exact diagnostic criteria. In persons older than age 60 years, prevalence estimates for overall MCI have varied from as low as 1% to 5% to as high

TABLE 50.3 Stages of Alzheimer Disease[a]

Stage of Alzheimer Disease	Cognitive Signs and Symptoms	Functional Impairment	Biomarker Status
No disease	None	None	Negative
Presymptomatic disease (preclinical Alzheimer)	None	None	Positive
Symptomatic predementia (mild cognitive impairment)	Single or multidomain	Not significant	Positive
Symptomatic dementia (Alzheimer disease)	Multiple domains	Definite impairment	Positive

[a]This formulation is the result of the National Institute on Aging and Alzheimer's Association workgroups, as published in 2011. Biomarkers include structural magnetic resonance imaging (regional hippocampal atrophy), positron emission tomography metabolic imaging (bitemporoparietal hypometabolism), positron emission tomography amyloid imaging (evidence of amyloid), and cerebrospinal fluid (low β-amyloid 42, high tau, and high phospho-tau).

FIGURE 50.1 Mild cognitive impairment (MCI) on the spectrum of neurodegeneration. The figure shows schematic increases over time in brain biomarkers (red line), symptoms (blue line), and functional deficits (green line). For Alzheimer disease (AD), biomarkers include (1) evidence for fibrillar β-amyloid accumulation in the brain through florbetapir, florbetaben, or flutemetamol imaging or because of low cerebrospinal fluid β-amyloid 42 and (2) evidence of neurodegeneration indicated by decreased hippocampal volume, decreased gray matter gyral thickness, or increased tau and/or phospho-tau in the cerebrospinal fluid. Symptoms would include memory, language, visuospatial, or executive dysfunction confirmed on neuropsychological testing. A disease-free (*at-risk*) period is followed by an asymptomatic but biomarker-positive period (*presymptomatic*), followed by a *symptomatic* period. This latter period consists of an intermediate, earlier time period marked by cognitive symptoms without significant effect on function (*MCI*) and a later time period in which cognitive symptoms are more evident and there is concomitant functional impairment (*dementia*).

as 30% to 40%. Studies of populations older than age 75 years in North America and Europe suggest a convergent estimate of prevalence of about 20%, most of which is amnestic MCI or amnestic multidomain MCI. Incidence rates of overall MCI vary in different reports from as low as 10 to as high as 200 cases per 1,000 person-years, depending on exact age range of elderly, the population studied, the numbers of years followed, and the exact criteria applied.

Risk factors for MCI appear to be the same as the risk factors for dementia conditions, notably Alzheimer disease (see Chapter 51). Age is the dominant risk factor. Gender has not proven to be a risk factor when controlling for age. Lower education has generally been found to be a risk factor, as sometimes has ethnicity, medical illnesses including cardiovascular disease, and genetic factors, including apolipoprotein E (APOE) ε4 allele. If a case of MCI ultimately progresses to a particular dementia, then retrospectively, it is found that the risk factors for that form of MCI were those for the dementia disorder. However, for the MCI patients who improve over 1 to 3 years, or stay stable, and do not progress to dementia, the major risk factors, in retrospect, are often psychiatric illnesses, including depression and anxiety, and reversible medical conditions.

Overall, adults aged 50 to 60 years or younger without a family history of early-onset dementia, presenting with subjective memory complaints, with or without objective confirmation, are more likely to have an underlying psychiatric basis to their dysfunction than are elderly persons. This is likely due to the fact that early dementia is less common in young and middle aged adults, anxiety and depression as primary psychiatric disorders are common in young and middle aged adults, and anxiety and depression rarely present de novo in the elderly.

PATHOBIOLOGY

The pathobiology of MCI is that of the disorders for which it is a precursor state. Thus, if MCI is an early form of Alzheimer disease, then Alzheimer pathology is the substrate. Correspondingly, if the MCI is a precursor to frontotemporal dementia (FTD), then the pathology is that of FTD. Thus the condition, as presently defined, is not a homogeneous clinicopathologic entity. The reader is referred to Chapter 12 on the dementias and the individual chapters covering specific causes of dementia later in this section.

DIAGNOSIS

The early and primary MCI consensus criteria have been shaped around the fact that MCI most often is prodromal for Alzheimer disease, reflecting the epidemiology of dementia. These criteria are detailed in this chapter's "Introduction" section and shown in Tables 50.1 to 50.3 and Fig. 50.1. More recently, there have been efforts to develop MCI criteria potentially predicting other neurodegenerative diseases, including dementia with Lewy bodies, Parkinson disease dementia, FTD, and vascular cognitive impairment. It is estimated that a quarter to one-half of patients with Parkinson disease have MCI, is most associated with the akinetic rigid phenotype of PD, and is found more often in older individuals. The cognitive domains that are affected and the quantitative cutoffs are not yet formalized but generally identify impaired attention/executive function and memory impairment. In dementia with Lewy bodies (DLB; further reviewed in Chapter 53), the second most common neurodegenerative dementia, there are now three recognized prodromal stages, including an MCI presentation, which may be similar to the Parkinson disease MCI phenotype but with more profound impairments identified in those perhaps reflecting early fluctuations seen later in DLB. Psychiatric onset of DLB is a third form, in which patients may present with late-onset major depressive disorder or psychoses seen in more apparent later stages of DLB; some patients with this presentation may present with severe symptoms requiring hospitalization. Parkinsonian features may be an additional diagnostic clue but may be difficult to discern from medication side effects for those patients treated with antipsychotics. Other DLB features including rapid eye movement sleep behavior disorder can occur in isolation, sometimes years before other cognitive or behavioral features and can be seen in other synucleinopathies or disorders with brainstem pathology.

The earliest stages of MCI in FTD are largely based on well-characterized family studies with known deterministic genes and reflect minor syndromic deficits of later stage presentations, including executive/attention deficits and language impairment. A cerebrovascular basis of MCI may be invoked if a patient has demonstrable evidence of large- or small-vessel strokes in the absence of other clinical or biomarker-based evidence of alternative neurodegenerative disease.

Several other terms potentially relatable to MCI have emerged but have not been as broadly adopted as the MCI framework.

Motoric cognitive risk syndrome describes patients with slow walking speed and subjective cognitive complaints. The underlying neuropathologic changes have not been described and its use may be limited to serving as a screening construct in geriatric primary care settings. *Mild behavioral impairment* formalizes what is may be described by care partners as a "personality change" and encompasses changes in motivation, affective regulation, social appropriateness, impulse control, or thought/perceptual content, which may be seen in FTD or frontal manifestations of other neurodegenerative diseases including Alzheimer disease. More detail is provided on the clinical presentations of FTD and Alzheimer disease, including behavioral features, later in this section.

Clinical Features

MCI manifestations are subjective and objective cognitive impairment (see Table 50.1), but each of the cardinal aspects of MCI has interpretative leeway. Generally, a diagnosis of MCI requires a "consistent" symptomatology not single disturbing events. Corroboration of a patient's symptoms by a knowledgeable informant also increases likelihood that the symptoms represent abnormal cognition. Assessment of objective memory and cognitive impairment depends on the exact domains (memory, language, attention, executive, and visuospatial function), the tests used for each domain, and the criteria for abnormality. Different standards have been used, including 1, 1.5, or 2 standard deviations below the normative mean, without formal consensus or agreement on which of these is most appropriate.

Assuming the unequivocal presence of subjective and objective cognitive changes, often the most diagnostically difficult criteria to assess is that of relative preservation of function. Particularly in the elderly, depending on their spousal or family support and on their residential environment, the patient may not be expected or in the habit of performing routine functions commonly performed earlier in life. Bills may be prearranged, meals may be preprepared, and travel may be circumscribed or always accompanied. In these settings, it is often difficult to assess what is evidence of significant functional decline. Even persons engaged in their occupation may have a narrow range of responsibilities and well-learned skills in their occupational field that makes decline in function inevident.

Diagnostic Testing

The diagnostic workup in MCI typically takes on two parallel paths, including laboratory- and imaging-based workup and neuropsychological testing through either screening tools and comprehensive assessment when possible. Laboratory and imaging studies have two potential roles. The first role is to exclude nonneurodegenerative medical conditions not evident on the clinical examination that might be responsible for the cognitive impairment and might be reversible with known therapies. The second reason is to discern biomarkers whether in cerebrospinal fluid or on brain imaging that might be of value in assessing the prognosis of the MCI state and whether it is more or less likely to progress to a dementing disorder.

Neuropsychological Testing

Neuropsychological testing may have even greater use in the case of suspected MCI than in dementia. Psychometric test results can be helpful in establishing the extent of cognitive impairment, the domains affected, and the degree to which there is impairment, in comparison to a normative sample of others with comparable age, sex, and education. Subtle differences can often be important in formulating regional involvement and thus diagnosis and can be lost later in the course of cognitive decline including dementia. Neuropsychological testing strongly informs the diagnosis of MCI and also provides a baseline for subsequent evaluations.

Laboratory Testing and Neuroimaging

Laboratory exclusionary tests are the same as those used in the workup of Alzheimer disease and other dementias (see Chapters 12 and 51) and include blood laboratory testing to assess the presence of renal or hepatic dysfunction; vitamin B_{12} deficiency; thyroid deficiency; and in some cases, infectious diseases such as Lyme disease, syphilis, or human immunodeficiency virus infection. Routine neuroimaging using magnetic resonance imaging (MRI) is often reasonable to exclude structural disorders representing infections, tumors, traumatic, hydrocephalic, or vascular injuries and may also provide information on pattern of brain atrophy indicative of an underlying process (see the following text). A noncontrast computed tomography of the brain is often sufficient to exclude these concerns if an MRI is not possible or practical. Electroencephalography or other neurophysiologic measures are rarely needed, unless there is the suggestion of some episodic nature to the symptoms suggesting the possibility of complex partial seizures. Electroencephalography is typically normal or shows nonspecific mild temporal slowing or diffuse background rhythm slowing. Cerebrospinal fluid testing is optional. Like MRI, it may rarely reveal the unlikely presence of an unsuspected contributory condition that might have its own specific therapeutic approach. Such disorders include central nervous system inflammatory, infectious, or neoplastic disorders, including neurosyphilis, neurosarcoidosis, or meningeal carcinomatosis.

Biomarker-Based Assessments

To determine the etiology of MCI and assist with prognostication, a number of tests have been shown to be of value in assessing the likelihood of progression of cognitive symptoms of MCI to dementia (Table 50.4). These tests include structural neuroimaging, molecular neuroimaging, and examination of cerebrospinal fluid biomarkers and genetic biomarkers. Although predictive, they are primarily used in research studies focused on MCI, are not currently supported by most insurances, but may have relevance to clinical practice should disease-modifying therapies become available.

The biomarker-based assessments are largely shaped around Alzheimer-based biomarkers because some of the other neurodegenerative disorders lack a suggestive profile other than the absence of suggestive incipient Alzheimer disease biomarker profile. Taken together, they are used similarly to a research diagnostic construct used in Alzheimer disease, which intends to identify the combinations of three principal biomarker-based hallmarks of Alzheimer disease: evidence of β-amyloid deposition ("A" through amyloid positron emission tomography [PET] or cerebrospinal fluid Aβ42), tau biomarker ("T" via cerebrospinal fluid phospho tau or tau PET), and neurodegeneration or neuronal injury ("N," through fluorodeoxyglucose-PET, structural MRI, or cerebrospinal fluid total tau). As detailed in Chapter 51, there is a very strong association with Alzheimer disease when all three are evident, or when two including amyloid

TABLE 50.4 Biomarkers Useful in Prognostication for Mild Cognitive Impairment[a]

Biomarker	Result	Prognostic Implications
Brain MRI	Focal decreased hippocampal volume, parietal gyral atrophy, or cortical thinning	Likely AD
Fluorodeoxyglucose PET imaging	Bitemporoparietal hypometabolism Frontal or anterior temporal hypometabolism Occipital hypometabolism	Likely AD Suggestive of FTD Suggestive of PCA or DLB
Florbetapir, florbetaben, or flutemetamol PET imaging	Positive signal for fibrillar amyloid	Suggestive of AD with or without involvement of DLB
Ioflupane SPECT imaging (DAT)	Decreased unilateral or bilateral striatal uptake	Suggestive of DLB
Cerebrospinal fluid biomarker analysis	Low β-amyloid 42 High phospho-tau	Suggestive of AD
Apolipoprotein E genotyping	ε4 Allele present	Suggestive of underlying AD

Abbreviations: AD, Alzheimer disease; DAT, dopamine transporter single photon emission computerized tomography; DLB, dementia with Lewy bodies; FTD, frontotemporal dementia; MRI, magnetic resonance imaging; PCA, posterior cortical atrophy; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

[a]The above assessments are useful in research-based studies of MCI and are anticipated to have broader clinical implications should disease-modifying therapies become available.

are evident, and less so with other combinations. Cautious use of these biomarkers is warranted in MCI and subjective cognitive impairment, in which these tools are presently intended to shape a differential diagnosis and not inform a presymptomatic clinical diagnosis. This approach is expected to be increasingly informative as the field remains collectively hopeful for disease-modifying therapies for neurodegenerative diseases.

In MCI, structural MRI may show patterns of cerebral atrophy, which can be suggestive of the presence of a particular neurodegenerative disorder. Early Alzheimer disease is marked by temporal lobe and parietal lobe gyral atrophy and cortical thinning. Studies show that temporal lobe atrophy is associated with a greater risk of progression of memory symptoms and development of Alzheimer dementia. FTD is more often marked by asymmetric or symmetric frontal and anterior temporal atrophy (see Chapter 52). Molecular neuroimaging using PET imaging tracers for amyloid such as florbetapir, florbetaben, or flutemetamol may show the early deposition of fibrillar β-amyloid indicative of the presence of neuritic plaques. Positive amyloid imaging is a strong risk for progression of MCI to dementia due to Alzheimer disease, and negative amyloid imaging makes it less likely to predict Alzheimer disease, although various cutoffs for imaging have been used. Most recently, flortaucipir, a PET imaging tracer for neurofibrillary tau, has been approved for use to estimate the density and distribution of aggregated tau neurofibrillary tangles in persons with cognitive impairment being evaluated for Alzheimer disease; its sensitivity and specificity were based primarily on persons with advanced disease. Cerebrospinal fluid biomarkers, particularly, the presence of low β-amyloid 42 but also likely the presence of high tau and phospho-tau, are associated with MCI progression to Alzheimer disease. Biomarkers for MCI due to DLB reflect those for dementia due to DLB and include reduced dopamine transporter uptake in the basal ganglia as seen on DAT–single-photon emission computed tomography or fluorodeoxyglucose-PET, polysomnogram evidence of rapid eye movement sleep without atonia, and abnormalities on myocardial scintigraphy (using the cardiac tracer metaiodobenzylguanidine, MIBG). Genetic testing for *APOE* genotype is not recommended in the workup of MCI regardless of suspected underlying diagnosis. As detailed in subsequent chapters in this section, the genetics of dementias are distinct and complex, and persons diagnosed MCI with a family history of dementia may benefit from genetic counseling with or without eventual testing (genetic counseling is further discuss in Chapter 35). The combinations of these factors in which multiple markers indicate the same incipient disease process are likely of even greater prognostic value, although correspondingly, the presence of discordant biomarkers makes prognostication of progression less clear.

TREATMENT

Because many cases of MCI, particularly amnestic MCI, develop into Alzheimer disease over time, a number of investigations have examined whether any of the four commonly used disease-specific treatments available for Alzheimer disease are of any benefit in either improving cognition or delaying the time period to conversion to dementia. The three cholinesterase inhibitors donepezil, galantamine, and rivastigmine have all been the subjects of trials in MCI. Only donepezil (10 mg/d) showed some mild evidence LEVEL 1[1] of efficacy in delaying progression to a diagnosis of Alzheimer disease (sometimes termed *conversion*). Galantamine trials showed a small degree of increased mortality in drug treatment compared to placebo, but it is suspected that this was a statistical finding, not necessarily indicative of an injurious effect of this drug in MCI. The sole approved noncholinesterase inhibitor Alzheimer medication memantine has been tried in MCI and mild Alzheimer disease and has been found to be inefficacious.

Disease-modifying treatments are not yet available for MCI, Alzheimer disease, or other neurodegenerative dementias. The wide presumption is that if a medication is shown to slow the progression of neurodegenerative disease, then that treatment given at the MCI stage would be even more useful than treatment of more advanced states beginning with mild dementia. Furthermore, even it is presumed that if a drug worked equally effectively at different stages of the disease, slowing progressive disease earlier would be more beneficial than slowing it later. Thus, increasingly prospective investigational therapies for Alzheimer disease are also being tested in subject populations with MCI. Imaging biomarkers for β-amyloid and tau, cerebrospinal fluid biomarkers for β-amyloid, tau, phospho-tau, synuclein,

and others and genetic markers including APOE genotype may be useful in predicting which persons with MCI are most likely to be in the early phases of Alzheimer disease. However, a biomarker-based approach to guiding treatment is principally used in research paradigms and is not standard clinical practice.

MCI also frequently involves concurrent anxiety or depression. In some cases, as mentioned earlier, the primary etiology of the MCI state may be depression. Thus, for any individual with anxiety or depression, consideration should be given to treatment of the psychiatric symptoms with antidepressants, most commonly selective serotonin reuptake inhibitors such as fluoxetine, sertraline, paroxetine, citalopram, or escitalopram.

In the period immediately following the diagnosis of MCI, patients and families are highly motivated to seek more information on MCI and dementia. This period presents a good opportunity for education, providing anticipatory support, referral into research studies, and discussing advance care planning (discussed further in Chapter 158). Although there is much interest in preventative strategies to address conversion from MCI to more obvious dementia, epidemiologic associations with potentially protective adulthood habits (eg, diet, exercise, and cognitive leisure) have not translated into clear evidence of protective cognitive benefit in randomized trials of nonpharmacologic interventions focused on diet, exercise, and cognitively engaging activities. Potentially modifiable cardiovascular and stroke risk factors should be addressed, given associations between these and cognitive decline regardless of presumed underlying neuropathology of MCI.

OUTCOMES

MCI is not a pathologically specific diagnosis, so the epidemiology of progression to dementia is most relevant to anticipating outcomes. It is clear that the majority of persons meeting criteria for MCI do progress to dementia over a period of 5 to 10 years. Both the rate of such progression and the particular dementia to which there is progression vary, in part depending on severity and in part depending on the type of MCI. Overall, amnestic MCI and amnestic multidomain MCI both most frequently progress to Alzheimer disease, and community-based studies estimate rates of progression to dementia between 5% and 20% per year. Some other less common forms of MCI, such as single-domain visuospatial MCI, may upon progression best fit the clinical syndromic diagnosis of posterior cortical atrophy, which, however, usually still reflects underlying Alzheimer disease pathology. Over the course of a few years, some persons with MCI remain relatively stable or even improve, although this course is more common in nonamnestic forms. Even persons who "revert" from MCI to normal cognition are at higher future risk of dementia. However, some persons remain stable with a diagnosis of MCI for many years, and the underlying basis of their dysfunction is unclear, as is their ultimate prognosis.

Alzheimer Disease 51

Lawrence S. Honig and James M. Noble

KEY POINTS

1. Alzheimer disease (AD) is the most common neurodegenerative dementia and is the underlying cause of memory loss in most cases of dementia.
2. AD neuropathologic changes, including amyloid and tau deposition, are thought to cause symptoms when directly impacting cortical structures or related networks.
3. Other symptoms of AD include impairments in language, visuospatial, executive, and motoric abilities, alone or in combination, with or without concomitant amnesia.
4. Workup for AD includes exploring for reversible causes of dementia, through clinical evaluations coupled with laboratory and imaging based assessments.
5. Fluid and imaging based biomarkers of amyloid and tau burden are available for use in forming a specific AD diagnosis and may have a role in prognostication and monitoring.
6. Current treatment options are palliative and provide symptomatic relief through central cholinesterase inhibition and the *N*-methyl-D-aspartate antagonist memantine.
7. Additional pharmacotherapies target behavioral and psychotic features, which may be faced by some but not all patients affected by AD.

INTRODUCTION

The most common dementia is Alzheimer disease. The disease was first named by Emil Kraepelin in 1910, after Alois Alzheimer, who in 1906 had described the clinical features and pathologic manifestations of dementia in a 51-year-old woman. For some decades, Alzheimer disease was considered a presenile form of dementia, affecting individuals with symptoms beginning before age 65 years. But the mid-20th century brought the understanding that the same clinical, pathologic, ultrastructural, and biochemical features of presenile Alzheimer disease are shared by those with the more common "senile" (older than age 65 y) dementia. The disease is commonly sporadic, although susceptibility relates to a variety of genetic and potentially modifiable risk factors, which are further impacted by age. Uncommonly, the disease has an autosomal dominant inheritance pattern, particularly in younger persons.

EPIDEMIOLOGY

Alzheimer disease is a chronic disease of aging, and both the incidence and prevalence of disease increase with age. Prevalence estimates reveal that fewer than 1% of persons younger than age 65 years are clinically affected, but about 5% are affected at age 65 to 75 years, about 20% at age 75 to 85 years, and likely over 50% at age 85 years and older. The increasing prevalence with age is because the age-specific incidence, or the number of new cases arising over a specific period of time, rises steeply from less than 1% per year before age 65 years to about 6% per year for individuals aged 85 years and older. The average duration of symptoms from first noticeable symptoms until death is typically from 10 to 20 or more years. More recent community-based studies suggest that incidence has decreased slightly in later birth cohorts, but prevalence has remained static, likely reflecting longer disease duration and, in part, changes in care patterns.

It is presumed that both a mix of factors, considered potentially modifiable or nonmodifiable, or classified as environmental and genetic factors are involved in the risk of the disease, all of which are influenced by age. However, extensive investigations of environmental risk factors have not been as consistently linked with neuropathologic changes. Late-life depression is associated with Alzheimer disease, although the direction of causality is unclear—it is likely that depressive symptoms are often early manifestations of this dementing disorder. Similarly, hearing loss and poor oral health have been epidemiologically associated with dementia, but their potential pathophysiologic links remain uncertain. Traumatic head injury has been associated with increased risk of Alzheimer like symptoms, but neuropathologically show a mix of distinct taupathic changes, Alzheimer pathology, as well as Lewy bodies, with these copathologies being increasingly common in older populations. Likewise, diabetes and cardiovascular and cerebrovascular disorders have been associated with increased risk of dementia, but these may be due to additive ischemic injury to the brain, rather than a true increase in Alzheimer disease. Some other midlife and late-life potentially modifiable risk factors including healthy diet, regular exercise, and adequate sleep have been epidemiologically associated with lower incidence of Alzheimer disease, but late-life lifestyle intervention trials have not translated into either prevention or slowing of cognitive decline. Studies of identical twins show that they are not necessarily concordantly affected, so almost certainly there are some factors other than classic genetic ones. However, the main risk factors for development of Alzheimer disease, each small in and of itself, appear to be the members of a growing long list of genetic variations (**Fig. 51.1**).

Genetic Basis of Alzheimer Disease

Most Alzheimer disease is "sporadic" rather than a Mendelian dominant or recessive condition. However, a small proportion of the total number of persons with Alzheimer disease (<0.5%) have disease that is transmitted as an autosomal dominant identified monogenic familial disorder, commonly, but not always, with onset before age 65 years. Mutations in

FIGURE 51.1 Genetic markers of Alzheimer disease. As shown by allelic frequency in the population (x-axis) as well as penetrance (y-axis). PSEN1, PSEN2, and APP are genes for which mutations can lead to autosomal dominant inherited Alzheimer disease, although a particular mutation in APP can also be protective against Alzheimer disease. APOE, SORL1, and the other genes listed all have been shown to have allelic variation that affects risk of Alzheimer disease. (Figure created by Alan Renton, PhD, and provided courtesy of Alison Goate, D.Phil, Icahn School of Medicine at Mount Sinai, New York, NY.)

three genes, the amyloid precursor protein (APP) gene on chromosome 21, the presenilin 1 (*PSEN1*) gene on chromosome 14, and the presenilin 2 (*PSEN2*) gene on chromosome 1, result in such autosomal dominant forms of the disease beginning as early as the third decade of life, with essentially complete penetrance (see **Fig. 51.1**). In addition, trisomy 21, or Down syndrome, results in near certainty of Alzheimer disease pathology by age 50 years and in symptoms of the disease in those who survive long enough. Finally, there is a protective variant in APP (the "Icelandic" allele, A673T), which is highly correlated with protection from Alzheimer disease. There are at least 217 described different variants in *PSEN1*, and its pathogenic variants lead to the most common form of familial early-onset Alzheimer disease. Pathogenic variants in these three genes account for as many as half of the familial forms of early-onset Alzheimer disease, may be considered deterministic because of nearly complete correspondence between the genotype and phenotype, and seem to lead to increased production of amyloid-β (Aβ) or specifically the $A\beta_{42}$ peptide.

There is a higher risk of Alzheimer disease in first-degree relatives of persons with Alzheimer disease. Siblings of patients have about two- to threefold the expected lifetime risk of developing the disease. Monozygotic twins have significantly higher concordance of Alzheimer disease than do dizygotic twins. Some of the genetic risk relates to the ε4 polymorphism of the apolipoprotein E (*APOE*) gene on chromosome 19, which shows a strong association with onset of Alzheimer disease in the age range of 60 to 80 years. The ε4 polymorphism of *APOE* is a normally occurring variant of the gene present in about one-third of the unaffected American population but present in about two-thirds of those with late-onset Alzheimer disease. APOE has been called a *susceptibility* gene because possession of the ε4 allele, a polymorphism, does not always lead to Alzheimer disease. One APOE ε4 allele is associated with about a 2- to 3-fold increased risk, whereas having two copies is associated with a 5- to 10-fold increased risk. Overall, the population attributable risk associated with APOE ε4 is approximately 20%, making it one of the most important risk factors for the disease. However, it is also recognized that these risks may dramatically differ by race-ethnicity for reasons not entirely understood.

A large number of gene variants have now been identified that each conveys a smaller risk of Alzheimer disease than that of APOE ε4 (see **Fig. 51.1**). Several dozen such genes are currently identified including some involved in lipid biology, intracellular processing, or endosomal pathways, and others involved in inflammation or the immune response, cell migration, cytoskeleton, axonal transport, and microglial cell function. Other genes will likely be identified adding to the already complex genetic architecture of this disease.

PATHOBIOLOGY

Alzheimer disease pathology is marked by two specific neuropathologic features (**Table 51.1** and **Fig. 51.2**): extracellular amyloid plaques molecularly consisting in large part of a fibrillar aggregation of the 40 and 42 amino acid peptides $A\beta_{40}$ and $A\beta_{42}$ and intracellular neurofibrillary tangles, which consist of paired helical filamentous polymers of hyperphosphorylated tau protein. Although these specific features permit pathologic diagnosis of Alzheimer disease, it is likely that the symptoms of the disease relate primarily to extensive synaptic losses and

TABLE 51.1 Pathologic Hallmarks of Alzheimer Disease[a]

Macroscopic/Regional	Clinical Implications
Hippocampal atrophy	Memory impairment
Parietotemporal atrophy	Dysnomia/visuospatial impairment
Nucleus basalis cell loss	Attentional impairment
Microscopic	**Molecular Concomitant**
Neuritic plaques	$A\beta_{42}$ and $A\beta_{40}$ fibrillar aggregates with associated neuritic changes
Diffuse plaques	$A\beta_{42}$ and $A\beta_{40}$ fibrillar aggregates
Neurofibrillary tangles	Paired helical filamentous aggregates of phosphorylated tau protein
Synaptic loss	Not known—but accompanied by decreases in various neurotransmitters
Neuronal loss	Not known
Granulovacuolar degeneration	Intraneuronal vesicular changes

[a]List of pathologic hallmarks of Alzheimer disease, including macroscopic/regional changes and microscopic changes and their clinical and molecular correlates.

later to frank neuronal losses. Much of the earliest brunt of this injury is borne by the entorhinal region of the medial temporal lobe.

The senile neuritic plaques are spherical microscopic lesions with a core of extracellular Aβ infiltrated and surrounded by abnormal nerve fibers (neurites). The $A\beta_{40}$ and $A\beta_{42}$ peptides are derived from the APP, a transmembrane protein present in most tissues. A region of the APP resides within an intramembranous domain of intracellular organelles in neurons, and several proteolytic enzyme activities, known as *secretases*, are responsible for cleavage of the protein. When cleaved by α-secretase, a soluble peptide derivative of amyloid is formed. However, when the APP is cleaved by β-secretase, and subsequently by γ-secretase, the peptides $A\beta_{40}$ and $A\beta_{42}$ are generated. These Aβ peptide monomers aggregate, forming oligomers, and ultimately large polymers, a process that can be demonstrated in vitro and presumably results in the amyloid plaques observed histologically. It is thus not surprising that the three autosomal dominant genes for Alzheimer disease are the APP gene itself and the PSEN1 and PSEN2 genes, which contribute to γ-secretase activity. Although there is little doubt as to a pathologic role of APP products, it is not clear which products might be most re-

FIGURE 51.2 Top panel shows a cortical brain section immunohistochemically stained with antibody to β-amyloid. There are extensive stained extracellular deposits, which include plaques and also blood vessel staining in the white matter (amyloid angiopathy). **Bottom left panel** shows section stained with antibody specific for phosphorylated tau protein, and the intracellular stained deposits are neurofibrillary tangles. **Bottom right panel** shows a histochemical stained section (silver stained with the Bielschowsky method), visualizing both plaques and tangles.

sponsible for presumed neurotoxicity and synaptic losses: monomers, oligomers, polymers, or even other more soluble fragments. In addition to the parenchymal deposition of amyloid in Alzheimer disease, there is in nearly all cases amyloid angiopathy, which is amyloid deposition around meningeal and cerebral vessels. This condition is of varying severity and import in different patients but is accompanied by a propensity for hemorrhages, which may be microscopic, although visible on susceptibility-weighted magnetic resonance imaging (MRI), or macroscopic, with medium or large lobar hemorrhages. In a small proportion of patients, acute localized or diffuse brain edema may occur, now known as amyloid-related imaging abnormality (ARIA), including ARIA with "vasogenic edema" and/or sulcal effusion/exudate (ARIA-E), and ARIA with microhemorrhages and/or superficial hemosiderosis (ARIA-H) either spontaneously or after delivery of investigational antiamyloid therapies.

Neurofibrillary tangles are fibrillary intracytoplasmic structures within the neurons. Electron microscopy shows paired helical filaments of the microtubule-associated protein, known as *tau protein*. Normally, tau is a protein responsible in part for the axonal cytoskeleton, participating in microtubule assembly. In Alzheimer disease, hyperphosphorylated tau aggregates form, which are recognized in the electron microscope as twisted paired helical filaments and recognized in the light microscope as neurofibrillary tangles. Neurofibrillary tangles are not specific to Alzheimer disease, but in this disease, they occur first in the hippocampal formation and later are seen throughout the cerebral cortex. This apparent topographic spread of tangles has been codified as a staging system by Braak and Braak, including involvement of entorhinal (stages 1 and 2), hippocampal (stages 3 and 4), and neocortical (stages 5 and 6) regions. Tangles seem to increase in severity and extent with disease progression. This is more evident than is the case for amyloid plaques, which are often present even before symptoms and do not appear to correlate so highly with disease severity in autopsy tissues. Recent human in vivo imaging evidence suggests that amyloid deposition does indeed increase with disease, but it may "saturate" earlier than the formation of tangles. The relative injurious basis of these two hallmark pathologies is still not clear.

An important but nonspecific pathologic feature of Alzheimer disease is widespread, regionally specific losses of synapses and ultimately losses of neurons. Synaptic losses are accompanied by a wide variety of neurotransmitter deficits. These include particular decline in cholinergic terminals in the hippocampus and cortex, which apparently owes to early and prominent degenerative involvement of the nucleus basalis of Meynert, whose large cholinergic neurons project widely. It is this cholinergic deficit that informs the basis for symptomatic treatment of Alzheimer disease with drugs that increase cholinergic tone. Alzheimer disease is also variably marked by granulovacuolar degeneration of hippocampal pyramidal cells, which is a poorly understood pathologic feature, amyloid deposition in blood vessels, and glial changes. Finally, it is common in Alzheimer to have coexistent pathologies and pathologic case series support copathologies make dementia symptoms more likely at an earlier age or more apparent. Copathologies include intracytoplasmic inclusions of α-synuclein known as *Lewy bodies* or *Lewy neurites*. Lewy bodies are discussed in Chapters 53 and 86 because they represent pathologic hallmarks of Parkinson spectrum disease. They are present in as many as 35% of Alzheimer disease brains and even present in brains of persons with early-onset autosomal dominant Alzheimer disease, for example, due to PSEN1 mutations. Vascular lesions, in addition to amyloid angiopathy (discussed earlier), are another common coexistent pathology, occurring in 30% to 50% brains of persons with Alzheimer disease. These include microinfarcts, microhemorrhages, and lacunar or large-artery infarcts. It is likely that, when present, Lewy body pathology and vascular pathologies contribute to the phenotype in Alzheimer disease, leading to the term *mixed dementia*. However, most studies show that the burden of plaques and tangles is best correlated with the progressive dementia in Alzheimer disease. Other frequent copathologies with Alzheimer disease include TAR DNA-binding protein 43 (TDP-43) and aging-related tau astrogliopathy. Some of these copathologies may also occur in isolation and present with clinical symptoms potentially suggesting Alzheimer disease, including limbic predominant age-related TDP-43 encephalopathy (LATE). Another related pathology of aging is that of isolated neurofibrillary tangles, termed *primary age-related tauopathy* (ARTAG), which likely occurs on a continuum of cognitive aging. The placement of primary age-related tauopathy (PART) in relation to neuropathologic and clinical Alzheimer disease remains a formulation in process.

DIAGNOSIS

The first organized criteria for clinical diagnosis of Alzheimer disease were established in 1984 by a joint effort of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Association (previously known as *the Alzheimer's Disease and Related Disorders Association*). These criteria, the National Institute of Neurological and Communicative Disorders and Stroke-Alzheimer's Disease and Related Disorders Association criteria, consisted of three levels of clinical certainty: definite, reserved only for autopsy-confirmed cases, probable, and possible. The criteria included a history of progressive deterioration in cognitive ability, not explicable by other known disorders, involving memory and at least one other cognitive domain, and causing some significant disturbance of functioning in the patient. These criteria were endorsed by the American Academy of Neurology in 2001, with the additional provision of preferred laboratory tests, such as computed tomography (CT) or MRI, and optional laboratory tests, such as serologic testing for syphilis. However, over time, it became clear that these criteria were inadequate due to the requirements for memory involvement, functional disturbance, and the lack of reference to more modern and specific biologic imaging and fluid marker tests, referred to in the following text. New sets of criteria have been developed by consensus sponsored by the National Institute on Aging and the Alzheimer's Association, and these National Institute on Aging-Alzheimer's Association criteria provide for preclinical diagnosis, early symptomatic diagnosis without functional impairment (see Chapter 50), and presymptomatic diagnosis. An additional construct has attempted to establish clinical trajectories relative to various combinations of three principal biomarker-based hallmarks of Alzheimer disease: evidence of β-amyloid deposition ("A" through amyloid positron emission tomography [PET] or cerebrospinal fluid [CSF] $A\beta_{42}$), tau biomarker ("T" via CSF phosphorylated tau, or tau PET); and neurodegeneration or neuronal injury ("N," through ^{18}F-fluorodeoxyglucose PET, structural MRI, or CSF total tau),

suggesting a strong association with Alzheimer disease when all three are evident, or when two including amyloid are evident, and less so with other combinations.

Clinical Features

The signs and symptoms of Alzheimer disease present and evolve variably, with the most common early signs being subjectively and objectively impaired memory (see Chapter 12). Overall, there is slow progressive cognitive impairment, eventually affecting many cognitive domains.

Cognitive impairment is the hallmark of Alzheimer disease. Memory impairment is the most common presenting symptom, present in over 90% of affected patients. The difficulty with memory is most prominent for newly acquired information, so-called short-term memory, whereas immediate, or "working" memory, is typically unaffected. "Long-term memory" for remote events is relatively unimpaired in the early phases of the illness but ultimately is also severely affected. As the disease progresses, impairments in language and visuospatial function typically become more prominent (Fig. 51.3) as well as impairments in abstract reasoning and executive function or decision making. The increasing impairment in language and visuospatial function may be particularly evident on serial office testing (see Fig. 51.3). In some, language dysfunction may be the earliest feature, and one form of primary progressive aphasia, the "logopenic" variant primary progressive aphasia, is often due to Alzheimer disease. In these patients, word-finding difficulty, circumlocutions, and impaired repetition are commonly present; primary progressive aphasia is discussed further in Chapter 52. In other persons, visuospatial impairment, which may progress to the extent of complete cortical blindness, may be the presenting symptom of Alzheimer disease, and this syndrome is termed *posterior cortical atrophy*. Alzheimer disease can also present as a corticobasal syndrome (CBS), with prominent features of limb apraxia, myoclonus, gait disturbance, and cortical sensory loss. The CBS in Alzheimer disease is less likely than corticobasal degeneration in frontotemporal dementia to have alien limb phenomenon; language problems may also present earlier in Alzheimer disease-CBS than in amnestic Alzheimer presentations.

Behavioral dysfunction is present at some point in the course of most patients with Alzheimer disease. The most common symptoms are not only depressive, principally with apathy, but also irritability, agitation, insomnia, hypersomnia, decreased or increased food intake, dependency, disinhibition, and repetitive or compulsive activities. These symptoms, in some cases, likely relate to neuroanatomic changes but, in other cases, may represent reactive changes to cognitive incapacities. The most common psychotic symptoms in Alzheimer include periods of agitation when patients become convinced of their delusions. Auditory or visual hallucinations may occur in Alzheimer disease but should prompt consideration of an

FIGURE 51.3 Mental status testing in a patient with memory problems, for whom a diagnosis of Alzheimer disease was made in year 1. Over a 7-year period, the drawings show increasing impairment in constructional praxis—the ability to copy figures. **Top row** shows example provided to the patient, and subsequent rows are the patient's performance initially and in succeeding years. The patient was also asked each visit to write a full sentence of his or her choice. There is increasing difficulty with both penmanship and content.

alternative explanation or a copathology. Delusions frequently have paranoid ideation regarding theft or infidelity and also may involve misidentification of place or person; they are much more common than hallucinations. The presence of detailed visual hallucinations, in the absence of concomitant primary visual system disease, should be a clue as to involvement of Lewy body dementia (see Chapter 53) as primary (diffuse Lewy body disease) or contributing (Lewy body variant of Alzheimer disease) dementia disorders.

Functional decline results from both cognitive and behavioral features. Loss of employment, financial difficulties, marital or other family dysfunction, driving difficulties, and difficulties learning new technologies such as automobile controls, home entertainment device remote controls, computers, or home security systems are frequent.

Examination of the patient with Alzheimer disease typically reveals only impairments in mental state. The remainder of the neurologic examination is usually normal, especially in the mild to moderate stages. In the later stages of the disease, parkinsonian signs, including rigidity, bradykinesia, shuffling gait, and postural change, are not uncommon. These features may in some cases be solely a consequence of Alzheimer disease but in other cases may relate to concomitant involvement of Lewy body dementia (see Chapter 53). Primary motor and sensory functions are typically spared. Early symptoms of seizures or falling, or early signs of cortical motor or sensory dysfunction, cranial or motor neuropathies, or cerebellar dysfunction, should all strongly raise the possibility of some other form of dementia (see Chapter 12).

Diagnostic Testing

Neuropsychological Testing

Neuropsychological testing is useful in establishing the extent of cognitive impairment in terms of domains affected and in terms of degree of affectation compared to persons of comparable age, sex, and education (normative results). Examination of test results in comparison to persons of a similar group allows for better assessment than results on an absolute basis because of the general wide variation in performance on these tests, which relate in large part to education (see Chapter 31). Such testing can also be very useful in following progression of disease, particularly in early stage disease, to distinguish trajectories from normal aging or when depression is present.

Laboratory Testing and Neuroimaging

Routine laboratory examinations of blood, urine, and CSF are unremarkable in Alzheimer disease. Electroencephalography and other neurophysiologic measures are nonspecific, revealing background rhythm slowing or other changes not diagnostic of any particular brain condition. Likewise, routine imaging by CT or MRI does not reveal gross structural abnormalities other than atrophy, particularly early in the course of the disease. Later in the disease, significant cortical and subcortical atrophy, although not entirely specific, is typically observed (Fig. 51.4). Often in Alzheimer disease, a regional pattern atrophy involving temporal, parietal, and to a lesser extent frontal regions, can be apparent, often represents earliest and most involved neuropathologic Alzheimer changes can be seen. However, many pathologically proven cases do not show consistent patterns. Regional cortical

FIGURE 51.4 Magnetic resonance imaging T1-weighted structural images from two patients (**A** and **B**) with Alzheimer disease, including in each patient selected sagittal (**top rows**) and axial (**bottom rows**) images. **A** shows a pattern of atrophy most prominent in parietal regions. **B** shows a pattern of atrophy more prominent in temporal regions.

FIGURE 51.5 **A** shows images from a single patient who underwent an ^{18}F-fluorodeoxyglucose positron emission tomography scan. **Top row** shows sagittal sections, **middle row** axial sections, and **bottom row** coronal sections. The images demonstrate decreased brain metabolic activity in bilateral parietal, temporal, and to a lesser extent frontal regions. Note that in this color coding scheme, "cooler" colors such as *green* and *blue* are lower activity, and "hotter" colors such as *yellow*, *red*, and *white* are higher activity. **B** shows ^{18}F-florbetapir positron emission tomography scan in two individuals, with a *black* and *white* image display scheme, in which blacker represents higher uptake of florbetapir. Each row shows an example of an axial, sagittal, and coronal brain imaging slice. The **top row** is of a normal control individual who shows cerebral uptake of the radioligand only in the white matter. The **bottom row** shows the images of patient with Alzheimer disease, who shows extensive gray matter uptake of the radioligand throughout cerebral cortex including frontal, temporal, and parietal regions and basal ganglia.

thinning is also identifiable on MRIs but is limited to research settings at present.

Most importantly, it has become clear that both CSF and functional brain imaging, often when used together along with structural imaging, can serve as relatively sensitive and specific markers of Alzheimer disease (as covered here in subsequent "Biomarker-Based Assessments" section, Fig. 51.5, as well as Chapter 12) and can be of use in the differential diagnosis of this disorder.

Genetic tests are generally not recommended for diagnosis of Alzheimer disease. However, selected testing may be useful in the diagnosis in families with the rare early-onset autosomal dominant forms of Alzheimer disease. For sporadic or familial late-onset Alzheimer disease, the $\varepsilon 4$ polymorphism of the *APOE* gene is associated with a higher risk of the disease, but because at least one-third of persons with Alzheimer have no $\varepsilon 4$ alleles, and because some persons with even two $\varepsilon 4$ alleles are symptom free even in their 10th decade of life, the test does not provide sufficient sensitivity or specificity to be used for diagnosis and is not recommended.

Biomarker-Based Assessments

Measurements of CSF proteins (see Chapter 32) are established to be of use in the diagnosis of Alzheimer disease. Typically in Alzheimer disease, $A\beta_{42}$ is decreased in concentration, perhaps related in part to deposition of amyloid in the brain. Total tau protein is typically elevated, relating presumably to neurodegeneration and loss of axonal integrity. Phosphorylated tau is also elevated and more specific for Alzheimer disease because in this disorder, the tau protein is abnormally phosphorylated. Combined measures of the concentrations of these three biomarkers results in sensitivity and specificity each in the range of 90%. Of note, it is clear that changes in $A\beta_{42}$, tau, and phosphorylated tau can precede clinical symptoms and diagnosis of disease by up to 15 years. Blood analytes in serum or plasma have particular appeal as a noninvasive means of potentially establishing an Alzheimer disease diagnosis and monitoring progression or response to therapy. Plasma $A\beta_{40}$ and $A\beta_{42}$ measures are now commercially available in some areas. Some metrics of specific plasma phosphorylated tau isoforms have been especially predictive of cognitive decline in research settings and may be on the horizon for eventual clinical applications.

Brain imaging has become important in diagnosis of Alzheimer disease, can aid in early detection of disease, and may be helpful in research studies following treatment of the disease. Brain imaging includes "structural" imaging, "functional" imaging, and "molecular" imaging. Structural imaging techniques including CT and MRI are used to exclude other causes of dementia, such as tumors or strokes. However, in Alzheimer disease, structural imaging typically reveals dilatation of the lateral ventricles and widening of the cortical sulci, particularly in temporal and parietal regions (see Fig. 51.4). Such cortical atrophy is not specific for Alzheimer disease because it can be seen in some older individuals who function normally by clinical and neuropsychological testing. MRI approaches have been developed to measure precise volumetric changes in the brain, and these can be useful in differentiating Alzheimer disease from frontotemporal dementia and have been used in monitoring therapies with investigational drugs (see Chapter 22). Functional brain imaging techniques include single-photon emission

computed tomography (SPECT), PET, and functional magnetic resonance imaging (fMRI) (see Chapters 22 and 23). Although using different technologies, functional imaging techniques hold in common a sensitivity to brain metabolism—either glucose uptake in the case of ^{18}F-fluorodeoxyglucose PET or the closely correlated blood flow measures examined by technetium 99m hexamethyl-propylene-aminoxime-SPECT or fMRI. Studies using PET or SPECT reveal a characteristic pattern of hypometabolism and hypoperfusion in the mesial temporal and posterior parietal lobes, with preservation of function of the deep gray nuclei and the primary sensory and motor cortices (see **Fig. 51.5A**). With the superior spatial resolution afforded by fMRI, studies have begun to map patterns of dysfunction in smaller brain subregions of the medial temporal lobe, the general area where the disease is thought to begin. Within the hippocampal formation, high-resolution fMRI has shown that, in contrast to the early stages of Alzheimer disease that target the entorhinal cortex, normal aging involves the dentate gyrus, a neighboring hippocampal subregion. Finally, the most recent development in brain imaging is being able to detect the molecular features of Alzheimer disease: amyloid-containing plaques and neurofibrillary tangles. The first such molecular imaging reagent for detecting neuritic plaques in vivo was "Pittsburgh compound B" (whose chemical formulation is ^{11}C-6-OH-benzothazole-1), but there are currently three approved ^{18}F-labeled reagents: florbetapir, florbetaben, and flutemetamol, all of which have been shown through clinical and autopsy studies to show cortical binding of radioligand in Alzheimer disease (see **Fig. 51.5B**). The absence of cortical binding is inconsistent with Alzheimer disease. However, as might be expected for a disease that starts with small amounts of asymptomatic $A\beta_{42}$ deposition, a substantial fraction of clinically normal elders (eg, about 25% of those older than age 65 y, with increasing proportions in older age groups) do have some binding, consistent with the possibility that they may later develop Alzheimer disease. Most recently, an ^{18}F-labeled reagent flortaucipir for neurofibrillary tau is approved for use based on a high sensitivity and modest specificity for the presence of Alzheimer tau changes. In the United States, presently, amyloid and tau imaging have limited application because they are not supported by most if not all health insurance programs. Additional investigational radioligands for tau, inflammatory signal, and as well as SPECT and PET radiopharmaceutical reagents to examine dopaminergic systems, promise a greater armamentarium of advanced molecular imaging biomarkers that may assist in early diagnosis and assessment of disease.

MANAGEMENT

Therapies for Alzheimer disease are currently symptomatic and palliative, because there are no proven disease-modifying treatments, although some appear to be on the horizon. Nonspecific treatments for secondary symptoms of Alzheimer disease can be useful. These include treatment of depressive symptomatology with antidepressants including selective serotonin reuptake inhibitors. Likewise, treatment of psychotic symptoms such delusions and hallucinations as well as agitation and irritability can be managed with judicious use of antipsychotic medications. Side effects of these medications can be limiting, including drug-induced parkinsonism. Neuroleptics have, in some studies but not others, been associated with small increases in mortality from various causes. Anxiolytics such as benzodiazepines may also be used but are generally avoided due to adverse effects on cognition. Despite potential risks, pharmacologic treatment of behavioral symptoms with neuroleptics can be of major help to patients and their caregivers.

TABLE 51.2 Treatments of Alzheimer Disease[a]

Medication	Dosages	Presumed Mechanism
Donepezil hydrochloride	5-10 mg/d PR or 23 mg/d ER oral	Cholinesterase inhibition
Galantamine hydrobromide	8-24 mg/d PR or ER oral	Cholinesterase inhibition
Rivastigmine tartrate	3-12 mg/d oral or 4.5-13.3 mg/d transdermal	Cholinesterase inhibition
Memantine hydrochloride	5-20 mg/d PR or 7-28 mg/d ER oral	NMDA receptor inhibition

Abbreviations: ER, extended release; NMDA, *N*-methyl-D-aspartate; PR, prompt release.

[a]List of medications approved by the U.S. Food and Drug Administration specifically for Alzheimer disease. Donepezil and rivastigmine are labeled for use in mild, moderate, and severe disease; galantamine is labeled for use in mild and moderate disease; memantine is labeled for use only in moderate and severe disease. Donepezil and memantine are also marketed as combination therapies.

There are five disease-specific treatments available for Alzheimer at this time. These five medications are symptomatic and do not appear to modify disease course but have received U.S. Food and Drug Administration approval for specific treatment of the disease (**Table 51.2**) on the basis of level 1 randomized placebo-controlled trials. Four of these are cholinesterase inhibitors, which effectively increase synaptic levels of brain acetylcholine through inhibition of synaptic acetylcholinesterase, which normally hydrolyzes acetylcholine released from the presynaptic neuron into the synaptic cleft. Tacrine was the first such drug LEVEL 3,[1] but it is no longer in common use due to 4 times daily dosing and hepatotoxicity; it has only limited availability internationally at this point. The three cholinesterase inhibitors currently in common use are donepezil LEVEL 1,[2-4] rivastigmine LEVEL 1,[5] and galantamine LEVEL 1.[6] The evidence is that these three have similar mild efficacy in improving cognition and may also cause small improvements in behavior and function in patients with mild, moderate, or severe Alzheimer disease (see "Level 1 Evidence" in the following section). One other drug, memantine, has been approved for treatment only of moderate to severe Alzheimer disease, for which there is level 1 evidence LEVEL 1,[7,8] whereas such evidence is lacking for mild disease. Memantine is an activity-dependent *N*-methyl-D-aspartate receptor antagonist and provides an independent modest benefit in cognition, behavior, and function in persons with moderate to severe disease. This benefit occurs in both settings of monotherapy LEVEL 1[7] and concomitant therapy with cholinesterase inhibitors LEVEL 1[8] in such patients.

Disease-modifying treatments are not yet available. However, the increasing understanding of Alzheimer disease as a disorder characterized by accumulation of β-amyloid, and tau aggregates has given rise to a significant number of experimental drugs that have been studied or are currently under investigation. Current approaches to potentially ameliorating the course of Alzheimer disease include monoclonal antibodies or active immunizations designed to clear amyloid protein from the brain, β-secretase inhibitors designed to decrease intracerebral generation of β-amyloid, and other therapies proposed

to deter tau aggregation or neuronal dysfunction. As noted in the chapter on mild cognitive impairment (see Chapter 50) and earlier in this chapter, although there is much interest in Alzheimer's preventative strategies, epidemiologic associations with potentially protective adulthood habits (eg, diet, exercise, and cognitive leisure) have not translated into prevention or slowing cognitive decline in randomized trials. From a broader neurologic perspective, it remains important in patients with Alzheimer disease that medical diseases are addressed, such as appropriate management of hypertension and diabetes, in an effort to appropriately reduce the risk of stroke and related complications. Standard advice regarding nutrition and physical activity may portend to better general health and control of cardiovascular risk factors in aging patients independent of potential impact on Alzheimer disease.

OUTCOME

When persons live long enough with disease, the continuous process of Alzheimer changes results in complete incapacity, and ultimately death, from conditions associated with and complications of severe cognitive dysfunction and immobility. As the disease progresses, supportive care measures become increasingly important for both patient and caregiver, often focused on maintaining some progressively smaller modicum of independence while avoiding catastrophic injury. Complications of falls, other accidents, and hospitalizations can dramatically accelerate subsequent clinical decline and impairment. The final chapter of this book (see Chapter 158) extensively covers many end-of-life care decisions in advance of and including supportive and hospice care, which come to dominate the terminal period of Alzheimer disease. The overall course from first symptoms to death is often as long as 20 years. Typically, diagnosis is not made until the disease is well established clinically, but on a molecular basis in CSF or neuroimaging, it can now be identified years prior to first symptoms. Although it is common for clinical disease to progress at different rates person to person, it is unlikely that there is truly any "plateau" or temporary cessation of neuropathologic progression. The field remains hopeful that one of the many approaches in development, nearly all of which are focused on developing disease modifying therapy, will substantially slow or prevent decline in Alzheimer disease.

Frontotemporal Dementia 52

Edward D. Huey, Megan S. Barker, and Stephanie Cosentino

KEY POINTS

1. Frontotemporal dementia (FTD) most commonly presents as a disorder of behavior and executive function (behavioral variant).
2. FTD can also manifest as a disorder of language (primary progressive aphasia).
3. Primary progressive aphasia can be further classified into nonfluent, semantic, and logopenic variants.
4. FTD is associated with cortical volume loss in frontal and anterior temporal lobes with relative sparing of posterior parietal and occipital cortex.
5. The three major genetic causes of FTD are mutations in the *MAPT*, *C9orf72*, and *GRN* genes.

INTRODUCTION

Frontotemporal dementia (FTD) is the most common clinical presentation of frontotemporal lobar degeneration (FTLD). FTLD is clinically and pathologically heterogeneous and also includes corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), Pick disease, and amyotrophic lateral sclerosis (ALS) as well as several rare FTLD-related tauopathies (eg, argyrophilic grain disease, multiple system tauopathy with dementia). The term *FTLD* generally denotes pathologic diagnosis, whereas FTD describes a clinical spectrum. Two main FTD phenotypes are seen. One form is primarily a disorder of behavior and executive function (behavioral variant FTD [bvFTD]), and the second, less frequent form is primarily a disorder of language, termed *primary progressive aphasia* (PPA) and defined by predominant language impairment for at least 2 years. Classifications of PPA include nonfluent variant/agrammatic (nfvPPA), semantic variant (svPPA), and logopenic variant (lvPPA). Cases of "mixed" PPA have also been reported. Combinations of behavioral and language symptoms that do not fit clearly into defined clinical subtypes reflect overlapping distributions of neuropathology in prefrontal and anterior temporal regions and can be present at disease onset but typically become more frequent with advancing disease severity.

EPIDEMIOLOGY

Overall, FTD (including both behavioral and language phenotypes) is the fourth most common dementia (behind Alzheimer disease [AD], vascular dementia, and dementia with Lewy bodies), affecting 1% to 16% of all people with dementia. FTD is the most common dementia prior to age 60 years and approaches the prevalence of AD prior to age 65 years. Approximately, 60% of cases occur in individuals aged 45 to 64 years, while individuals aged 65 years and older comprise 20% to 25% of all cases. Although we do not yet have definitive epidemiologic studies, the estimated point prevalence of FTD in individuals younger than 65 years, based on studies primarily including Caucasians in North America and Europe, is 7 to 30/100,000. Of these, 20% to 40% demonstrate some aspect of PPA. Most studies implicate an equal distribution by gender, although there are reports that bvFTD and svPPA are more common in males, whereas nfvPPA is more common in females. It is currently unknown how the prevalence of FTD differs across ethic groups. When interpreting prevalence estimates, it is important to note that lvPPA was only added as a third PPA classification in 2011 and is most commonly associated with AD rather than FTLD pathology. Prior to 2011, studies categorized cases of PPA into semantic and nonfluent variants, or as "fluent" versus "nonfluent," and these binary categories captured cases that would go on to be reclassified as lvPPA. Therefore, the majority of studies reporting on the prevalence of FTD likely include cases of lvPPA in their estimates.

PATHOBIOLOGY

Gross frontal and temporal lobe atrophy is usually evident in FTLD (a pathologic diagnosis, not necessarily corresponding to a clinical diagnosis of FTD) patients at autopsy, with histopathology revealing neuronal loss and gliosis affecting superficial cortical lamina of these same cortical regions, along with absence of the typical pathologic findings of AD (except in the case of lvPPA). FTLD encompasses several different pathologies, including neuronal inclusions containing TAR DNA-binding protein 43 (TDP-43), tau isoforms, and fused in sarcoma/translocated in liposarcoma (FUS/TLS) protein. Some individuals will have clinical and/or pathologic evidence of ALS. ALS is most commonly associated with bvFTD but can co-occur with any of the clinical presentations of FTD (eg, PPA). As demonstrated in Figure 52.1, several gene mutations associated with FTLD result in specific neuropathologies and sometimes specific clinical presentations. Therefore, the clinician can infer the neuropathology based on some (eg, when ALS is present in the context of bvFTD), but not other (eg, lvPPA), clinical presentations.

Fewer than half of all bvFTD patients will demonstrate prominent tau aggregates, whereas approximately half of bvFTD patients will stain for ubiquitin, a nonspecific marker of cell death. However, the breakdown of pathologies across clinical subtypes differs. For example, while FTLD-tau is the most common pathology in bvFTD and nfvPPA phenotypes, TDP-43 pathology is the most common pathology in svPPA.

A major FTLD subtype associated with tau aggregates is Pick disease. First described by Alois Alzheimer, Pick disease is characterized by argyrophilic cytoplasmic tau inclusions (Pick bodies) and swollen neurons (Pick cells). Ubiquitin-positive cases of FTLD were recently discovered to be characterized by inclusions composed of aggregates of TDP-43 and more rarely

FIGURE 52.1 Association between pathologic, genetic, and clinical variants of frontotemporal dementia (FTD). Abbreviations: ALS, amyotrophic lateral sclerosis; CBD, corticobasal degeneration; PSP, progressive supranuclear palsy.

FUS. The clinical presentation of FTD-ALS is associated with TDP-43–positive FTLD (see Fig. 52.1).

GENETICS

An estimated 40% to 50% of cases of FTD are familial, but only 10% to 15% follow a clear autosomal dominant pattern. Mutations in three genes account for the great majority of cases of FTD with an identified genetic cause (see Fig. 52.1). The most common genetic cause of both FTD and ALS appears to be the hexanucleotide repeat expansion in *C9orf72* on chromosome 9. The phenotype associated with *C9orf72* expansions can be FTD, ALS, or combined FTD-ALS. This expansion accounts for approximately 35% to 40% of familial ALS, 6% of sporadic ALS, 25% of familial FTD (with or without ALS), 5% of sporadic FTD, and up to 88% of familial patients with both FTD and ALS.

The two other known major genetic causes of FTD are mutations in the *MAPT* (tau) and *GRN* genes. Like *C9orf72*, *MAPT* and *GRN* mutations are autosomal dominant with high penetrance. Tau binds to microtubules, and it exists in isoforms of three and four microtubule-binding domains generated by alternate splicing of exon 10. Deposition of three-repeat tau is associated with Pick disease, whereas four-repeat tau is associated with CBD and PSP. *GRN* is an oncogene that codes for the protein granulin, which is a growth factor involved in wound healing. Reduced levels of granulin are associated with FTD, but elevated levels of granulin are associated with certain tumors including teratomas and breast, esophageal, and liver cancers. This is similar to another FTD/oncogene, *FUS*, in which elevated levels are associated with sarcoma, but reduced levels are associated with FTD. Rare other genetic causes of FTD or FTD-ALS include mutations in valosin-containing protein (*VCP*), *TARDBP*, *TBK1*, *UBQLN2*, *CCNF*, *SQSTM1*, *CHCHD10*, *OPTN*, *TIA1*, and *CHMP2B*. Clinical genetic testing can be considered with the guidance of a genetic counselor. Until recently, it was generally thought that an FTD patient should have a first-degree relative with FTD or a related illness, such as ALS, to be offered clinical genetic testing. However, genetic testing of cases of FTD or FTD-ALS without a family history should be considered. Clinical presentation and pathology in family members can guide genetic testing; for example, whether to test only for known mutations or to sequence the entire gene that is associated with FTD, or even perform whole exome or whole genome sequencing.

CLINICAL MANIFESTATIONS

Behavioral Variant

The ventral prefrontal cortex is usually implicated in bvFTD and appears to play an important role in social cognition and behavior. Alteration in personality and behavior, reflecting impaired judgment of social norms, is a hallmark feature of bvFTD. Patients display a loss of social graces, generally characterized by decreased empathy, diminished reactions to emotional events, excessive familiarity with strangers or acquaintances, inappropriate jocularity, and a general lack of self-consciousness. Distractibility, impulsivity, and apathy are also components of bvFTD. Such symptoms may be subtle at onset. Patients may also present with stereotyped behaviors, involving movement, language, or more complex behaviors. Increased appetite and

hyperphagia, particularly for sweets, and hyperorality can also occur. Patients with bvFTD frequently demonstrate reduced awareness of or lack of concern for their symptoms. The apathetic and amotivational aspect of bvFTD may initially be mistaken for depressed mood; however, it is relatively rare for patients with bvFTD to endorse feelings of sadness or hopelessness. In fact, recent work found a lower prevalence of major depressive disorder among prodromal *MAPT* carriers destined to develop bvFTD and an elevated prevalence of atypical depression (eg, irritability, agitation) as compared to familial controls.

With regard to cognitive function, changes in behavior and social cognition are often observed at the earliest stages of the disease and even in prodromal in *MAPT* carriers. Formal neuropsychological testing most commonly reveals executive dysfunction and changes in language with preserved visuospatial functions. Language deficits in bvFTD tend to be subtle and not qualify as aphasia; for example, patients might exhibit poor narrative organization, tangential speech, and reduced spontaneous speech output. However, early semantic (eg, naming) problems have been reported in prodromal *MAPT* carriers (sometimes considered a "mixed" behavioral-semantic phenotype), and language presentations in bvFTD can be highly variable. Performance on measures of memory is also quite variable. The most recent diagnostic criteria for bvFTD (2011) allow for inclusion of individuals with atypical cognitive presentations such as those with severe amnesia or spatial disorientation. Finally, it is possible that objectively measured cognition can be within normal limits in patients with bvFTD despite marked behavioral changes in everyday life, or alternatively, performance may be globally impaired secondary to apathy, inattention, or stimulus-bound responding.

Primary Progressive Aphasia

The three PPA phenotypes broadly map onto disruption of different components of the language network, with nfvPPA reflecting left frontal perisylvian involvement, svPPA implicating the anterior temporal lobes, and lvPPA associated with left posterior temporoparietal compromise. nfvPPA patients generally demonstrate reduced speech output that is both effortful and dysgrammatic. Such symptoms may be preceded by anomia (problems with naming), subtle deficits in sentence construction, as well as apraxia of speech (ie, impaired motor planning and sequencing of the movements required for correct speech production). Comprehension is generally preserved, although patients may have difficulty decoding syntactically complex phrases. In contrast, svPPA is a fluent aphasia, with normal prosody and tempo, but patients have progressive loss of semantic knowledge (ie, understanding and recognizing the meaning of words and/or objects). Anomia and single-word comprehension deficits are the core diagnostic criteria. Surface dyslexia, the phonologic decoding or "regularization" of irregularly spelled words (eg, "*sue*" for *sew*), is also a feature of svPPA, reflecting loss of item-specific knowledge. Patients with svPPA are also described to present with fixations on and/or frequent questions about the meaning of a word (eg, "What is a comb?"). Behavioral changes are also typical of svPPA, including obsessive-compulsiveness and socioemotional changes characterized by indifference and lack of warmth particularly with differential right hemisphere involvement. There is evidence that the behavioral syndrome associated with svPPA overlaps with, but differs in some ways from, the behavioral symptoms in bvFTD. Another sign of compromise to right anterior temporal regions is prosopagnosia (inability to recognize faces). Finally, lvPPA is characterized by slow but generally grammatically correct spontaneous speech with frequent word finding pauses, difficulty naming, phonologic paraphasias (ie, use of an incorrect word that is phonologically related to or sounds like the intended word) as well as sentence repetition errors. Repetition errors are generally seen for sentences of increasing length and complexity rather than for single words or simple phrases and appear to reflect limited auditory short-term memory capacity. lvPPA is most often associated with AD pathology, reflecting FTD pathology in less than one-third of cases. There is some evidence that low episodic memory scores are predictive of AD pathology in lvPPA, but this is not always the case.

DIAGNOSIS

The diagnostic probability of FTD is heightened in those younger than 65 years and in those with an autosomal dominant pattern of inheritance. Rapidly developing knowledge regarding the phenotypes associated with FTD resulted in revisions to the diagnostic criteria in 2011. The new bvFTD criteria allow for heterogeneous presentation of disease as well as levels of diagnostic certainty (ie, possible, probable, definite), and the most recent PPA criteria (2011) include lvPPA as a third variant. In one neuropathologic case series, addition of the lvPPA diagnostic category resulted in reclassification of approximately half of cases that had been previously diagnosed as nfvPPA and improved separation of FTLD versus AD pathology.

The diagnostic workup for FTD relies heavily on cognitive and behavioral assessment. Formal neuropsychological testing can identify subtle language or executive dysfunction that aid in the differential diagnosis of FTD from other dementias, such as AD, as well as in the characterization of the FTD phenotype. In particular, nonverbal abilities such as spatial processing and nonverbal memory are usually relatively well preserved on formal testing of FTD patients. Regarding the cognitive profile of FTD versus AD, a common differential diagnosis, visuospatial functions are generally well preserved in FTD but poor in AD. The integrity of memory storage, measured through recognition testing and proportion of information retained after a delay, has traditionally served as a critical variable for differentiating FTD from AD. However, it is increasingly recognized that poor performance on these metrics is not uncommon in FTD. Moreover, the retrieval of information from memory may be equally impaired in both groups. With regard to PPA, language assessments can be tailored toward identifying the specific deficits that characterize the three variants, although mixed presentations are common and cases are often not clear cut.

In addition to the primary behavioral and language phenotypes described earlier, patients with FTD may present with or develop other neurologic signs; therefore, it is essential to perform a detailed neurologic examination in all suspected cases. Approximately 10% to 15% of patients with FTD exhibit signs of motor neuron disease consistent with ALS, and 20% to 30% of all patients with FTD display parkinsonism at some point. The presence of parkinsonian and other motor signs (eg, gait disturbance, limb rigidity, apraxia, dystonia) may suggest a diagnosis of CBD or PSP. Some patients will also present with psychosis, most frequently in the context of *C9orf72* or *GRN* mutations.

Magnetic resonance imaging in FTD often reveals cortical volume loss in the frontal and anterior temporal lobes with relative sparing of posterior parietal and occipital cortices (Figs. 52.2 and 52.3). Functional neuroimaging

FIGURE 52.2 Magnetic resonance imaging demonstrating frontal atrophy in a patient with behavioral variant frontotemporal dementia.

FIGURE 52.3 Sagittal brain magnetic resonance image of the patient shown in **Figure 51.3.**

(^{18}F-fluorodeoxyglucose positron emission tomography or technetium 99m hexamethylpropyleneamine oxime single-photon emission computed tomography) often reveals frontotemporal hypometabolism (Fig. 52.4). nfvPPA is associated with left-sided frontal perisylvian involvement and svPPA with anterior temporal involvement. Recent developments in tau-specific PET tracers may prove useful in diagnosing FTD in the future. Cerebrospinal fluid (CSF) findings include normal cell count and protein. CSF phosphorylated tau (p-tau)/total tau (t-tau) and Aβ42 levels have not demonstrated sufficiently reliable differences from controls to use as a diagnostic test for FTD. However, these protein levels can be useful in distinguishing FTD from AD, as patients with AD will usually show elevated levels of t-tau and p-tau and reduced levels of Aβ42 in CSF compared to controls and patients with FTLD. The combination of imaging and CSF biomarkers can greatly increase diagnostic accuracy. These tests can also be helpful in determining the neuropathologic process associated with certain clinical presentations such as lvPPA. The development of motor symptoms can elucidate the underlying pathology with symptoms of corticobasal syndrome (eg, apraxia, cortical sensory deficits, parkinsonism, dystonia) or PSP (decreased balance, vertical gaze palsy, axial rigidity) associated with underlying tau pathology and symptoms of ALS associated with underlying TDP-43 pathology. It is important to note that the differential diagnoses for FTD may include both neurodegenerative and psychiatric disorders.

MANAGEMENT

Currently, we do not have medications that have been shown to be disease-modifying therapies for FTD. Cholinesterase inhibitors do not appear to help (level 2 studies), although there is a rationale for treating lvPPA with cholinesterase inhibitors as it usually indicates underlying pathologic AD. Serotonergic antidepressants show some efficacy reducing certain behavioral symptoms including agitation and repetitive behaviors in level 1 and 2 studies LEVEL 2.[1] Atypical antipsychotic medications are also often used to attempt to reduce behavioral symptoms in FTD. Cognitive deficits and apathy generally do not improve with medication treatment. Memantine has not demonstrated efficacy for the treatment of the cognitive symptoms of FTD LEVEL 1.[2]

Management of FTD relies in large part on nonpharmacologic interventions. Foremost of these is patient and family education. At diagnosis, patients and families will want to know what to expect in the years to come. Genetic counselors can be useful for education about genetic testing. Referral to local support groups and to nationwide organizations can be helpful. A symptom diary can be a useful tool to track symptoms, especially behavioral symptoms, as the disease progresses, and to see the effects of therapeutic interventions as they are introduced. Environmental modifications, including locking doors and removing visible food, can be helpful for wandering behavior and hyperphagia. Providing only small portions on plates can also be useful in managing hyperphagia. Wander bracelets can improve safety and can be equipped with tracking systems such as GPS to help in finding the patient. Calendars and consistent routines can provide structure and predictability for the patient and may help in managing executive problems. Safety measures should be put in place (eg, locks on drawers/cabinets) for dangerous items, such as firearms or knives, due to impulsive behavior and poor judgment. Physicians should continually assess if the level of assistance provided to the caregiver is sufficient. Physicians should also consider whether the patient is able to continue driving or remain at work. The behavioral symptoms of bvFTD can put family members of patients at risk for physical injury or sexually inappropriate behavior toward minors. Children are often at greater risk for exposure to behavioral symptoms in FTD than in other types of dementia because the patients are frequently younger, more likely to have young children at home, and more mobile. These behaviors will likely necessitate placement out of the home. In the later stages of the illness, palliative care and hospice referrals can be helpful in managing symptoms.

OUTCOME

Knowledge on the natural history of FTD is limited to epidemiologic studies drawn from dementia specialty centers. The median time from first symptom onset to death ranges from 9.5 years for bvFTD (approximate range 3-16 y), to 8 years for nfvPPA (approximate range 3-12 y), to 12 years for svPPA (approximate range 6-18 y). Comorbid ALS shortens life span, with median survival of 3 years from symptom onset, although outliers with unusually long survival have been reported. Tau mutations are generally associated with a slower disease progression. The ways in which people die from FTD are similar to other types of dementia and include infection, often related to decreased mobility, aspiration, or incontinence, and decreased oral intake of food and water leading to dehydration and malnutrition.

Lewy Body Dementias 53

Oren Levy, Richard A. Hickman, and Karen S. Marder

KEY POINTS

1. Neocortical Lewy bodies, containing α-synuclein, are the defining pathologic finding in dementia with Lewy bodies.
2. Core clinical features of dementia with Lewy bodies include visual hallucinations, fluctuations in cognition, rapid eye movement sleep behavior disorder, and parkinsonism.
3. Abnormal dopamine transporter imaging provides strong evidence supporting a diagnosis of dementia with Lewy bodies.
4. Acetylcholinesterase inhibitors improve multiple cognitive and psychiatric features of dementia with Lewy bodies.

INTRODUCTION

Lewy body dementias (LBDs) refer to a group of dementias with prominent motor parkinsonism and α-synuclein pathology. The nomenclature in this area is confusing and warrants clarification. The LBD is a broad designation that includes two main disease entities: dementia with Lewy bodies (DLB) and Parkinson disease dementia (PDD). Indeed, part of the confusion arises from underlying uncertainty in the field about whether DLB and PDD are distinct disorders or represent different presentations of the same disease. Early dementia characterizes DLB, whereas PDD is used to describe dementia occurring later in the course of well-established Parkinson disease (PD). The "1-year rule" is a consensus guideline to distinguish the two: When cognitive impairments precede or appear within 1 year of the motor signs, DLB is diagnosed; the term *PDD* is used when dementia occurs more than 1 year after the onset of parkinsonism. This chapter focuses primarily on DLB.

EPIDEMIOLOGY

The DLB is considered to be a common cause of dementia, with an estimated worldwide population prevalence of 4.2% to 7.5% and incidence of 3.8% in those newly diagnosed with dementia. However, neuropathologic studies indicate that DLB comprises 15% to 20% of autopsied dementia cases. Although autopsy studies are typically small and prone to selection bias, they highlight the likelihood that the actual prevalence and incidence rates of DLB may be higher due to the difficulty of diagnosing DLB clinically. In larger studies, the average age at diagnosis is in the mid-70s. Men are likely more susceptible to DLB and have a worse prognosis than women.

PATHOBIOLOGY

Neuropathology

Common pathologic findings of DLB are summarized in Table 53.1 and illustrated in Figure 53.1. Lewy body (LB) pathology, particularly in the cortex, is the most important factor in the development of LBDs (Fig. 53.1A,C). The LB are the only essential feature in the pathologic diagnosis of DLB; other features are apparent in most but not all cases.

Lewy Bodies

The LB are eosinophilic intracytoplasmic neuronal inclusion bodies and are found in both the subcortical regions and brainstem as well as in the cortex in DLB (Fig. 53.1A). Brainstem LB occur in the substantia nigra and locus coeruleus. The term *cortical Lewy body* refers to less well-defined spherical inclusions seen in cortical neurons (Fig. 53.1B). Identification of cortical LB may be complicated by the presence of severe Alzheimer changes in some individuals and the paucity of cortical LB in some DLB cases.

Lewy Neurites

Lewy neurites are neurofilament abnormalities and a distinctive part of LB pathology in which proteins cluster into diffuse aggregates (Fig. 53.1C). They occur in the hippocampus (CA2/3 region), amygdala, nucleus basalis of Meynert, dorsal vagal nucleus, and other brainstem nuclei.

Alzheimer Pathology

Most cases of DLB demonstrate comorbid Alzheimer disease (AD) pathology including amyloid plaques and neurofibrillary tangles. Plaque types in DLB are classified as either diffuse/immature plaques with τ-positive neurites or diffuse/immature plaques with

TABLE 53.1 Pathologic Features Associated With Dementia With Lewy Bodies

Essential for diagnosis of DLB
- Lewy bodies

Associated but not essential for diagnosis of DLB
- Lewy-related neurites
- Plaques (all morphologic types)
- Neurofibrillary tangles
- Regional neuronal loss, especially in the brainstem (including the substantia nigra and the locus coeruleus) and the nucleus basalis of Meynert
- Microvacuolation (spongiform changes) and synapse loss
- Reduced concentrations of choline acetyltransferase (ChAT) in neocortex

Abbreviation: DLB, dementia with Lewy bodies.

FIGURE 53.1 Neuropathologic features of dementia with Lewy bodies (DLB). A: Photomicrograph of a cortical Lewy body (LB) within a diseased neuron of a patient with DLB (layer V, precuneus, original magnification: 630×). The LB within the cortex lack the characteristic halo around the circumference of the inclusion, which is in contrast to brainstem LB. B: Photomicrograph of DLB showing spongiform change that is histologically reminiscent of Creutzfeldt Jakob disease (layers V-VI, anterior temporal pole, original magnification: 100×). C: Immunohistochemical stain against α-synuclein labels widespread LB within the infragranular layers of the cortex (layers V-VI, occipitotemporal gyrus, original magnification: 100×). C': A Lewy neurite within the cortex is labeled by an α-synuclein immunostain. Abbreviations: GM, gray matter; WM, white matter.

τ-negative, ubiquitin positive neurites. Biochemical studies have shown that α-synuclein deposition promotes the intracellular aggregation of τ- and β-amyloid in cell models, providing a potential mechanism that contributes to the frequent co-occurrence of AD pathology.

Spongiform Change/Microvacuolation

This is a feature of some DLB cases and occurs mainly in temporal cortex. It may relate to the severity of the disease. These spongiform changes are similar to those seen in Creutzfeldt-Jakob and prion-related diseases. Although there is considerable interest in the "prion hypothesis" of α-synuclein aggregation and spread, there is currently no evidence that DLB is a transmissible disorder.

Distinction Between Dementia With Lewy Bodies and Parkinson Disease Dementia

Although there are many histologic similarities between DLB and PDD, subtle morphologic differences between the two diseases are becoming apparent through neuropathologic studies. First and foremost, neuronal loss in the substantia nigra may be more extensive in PDD than in DLB. There are now reports of a greater amyloid burden and neuritic plaque score in DLB than in PDD and that there tends to be a greater α-synuclein burden within the temporal and parietal cortices in DLB. An increased amyloid burden has also been suggested within the caudate nucleus and putamen in DLB than in PDD. Further investigation is needed to draw out the pathologic differences in the spectrum of DLB and PDD.

Neurotransmitter Systems

The exact mechanisms leading to dementia in DLB are unknown. However, there is an association between structural neuropathologic findings in DLB, dopamine depletion and noradrenergic, serotonergic and cholinergic dysfunction. The LB have a predilection for the substantia nigra, and DLB is characterized by dopaminergic changes in the striatum and frontal cortex, leading to parkinsonism. In addition to motor control, dopamine is involved in a range of nonmotor behaviors such as cognition, motivation, sleep, and mood. The cholinergic nucleus basalis is another susceptible region, leading to widespread and severe cortical cholinergic deficits. Lewy pathology may also affect brainstem nuclei such as the locus coeruleus, which receives noradrenergic activation, and the serotonergic raphe nuclei. All of these areas are known to be involved in modulation of cognitive and psychiatric symptoms.

Genetic Risk Factors

The majority of genetic studies in DLB have used a candidate gene approach and have relied on clinically diagnosed DLB. The first genome-wide association study was performed in 2017 in 1,743 cases of DLB (1,324 pathologically proven). The heritability of DLB has been calculated to be 36%, similar to PD. The DLB has been shown to be genetically correlated to both AD and PD, but there is consensus that there are yet to be identified unique genes associated with DLB. Three genes have been consistently associated with DLB: *APOE*, *SNCA*, and *GBA1*.

APOE

The most consistent risk factor for DLB (as well as PDD) is *APOE* ε4. Although the association of *APOE* ε4 and DLB was thought to be mediated by the presence of AD-related neuropathology, it has been shown to be a risk factor even among cases of "pure" DLB with minimal AD pathology. In a series of 652 autopsy confirmed LBD and 660 controls, *APOE* ε4 was associated with risk of diffuse LBD regardless of the degree of AD pathology. Furthermore, the presence of *APOE* ε4 was associated with the severity of LB pathology independent of AD pathology.

SNCA

The *SNCA* gene encodes the α-synuclein protein, which aggregates in neurons to form LB. Point mutations in *SNCA* (p. Ala53Thr and p. Glu46Lys) as well as locus multiplications (three and four copies of *SNCA*) have been associated with familial cases of parkinsonism and dementia with DLB phenotypes. There are different single-nucleotide polymorphism within the *SNCA* gene associated with the risk of PD and DLB. Pathogenic changes in the *SNCA* gene may increase the probability of the protein to aggregate. In addition, changes in *SNCA* expression levels and distribution are also likely to affect disease risk and phenotype (ie, PD vs DLB).

GBA1

Several individual studies and an international multicenter collaborative study have demonstrated that patients with PD who carried mutations for the lysosomal enzyme glucocerebrosidase (*GBA1*) have a higher incidence of PD-mild cognitive impairment (MCI) and PDD. Other multicenter autopsy studies have demonstrated that subjects with DLB were more than 8 times more likely to carry a *GBA1* mutation than were controls. Further analyses indicate that *GBA1* mutations are also significantly associated with earlier age at onset and death in DLB. Although mechanisms underlying *GBA1*-associated parkinsonism and dementia are still not completely understood, accumulating evidence suggests that impairment of the aging lysosome, enhanced by deficient or mutant glucocerebrosidase, can affect α-synuclein degradation.

CLINICAL MANIFESTATIONS

Cognitive Impairment

The diagnosis of DLB presupposes the presence of dementia, that is, cognitive decline sufficient to interfere with function and/or activities of daily living. Early signs of cognitive impairment in patients with DLB include executive dysfunction, visuospatial impairment, and deficits in verbal memory. Executive dysfunction is a hallmark feature of DLB and includes impairment in set shifting, attention, and planning. Memory deficits in DLB are to be related to retrieval of learned information, which is improved by cuing.

The Mini-Mental State Exam (MMSE) is less sensitive to the earliest cognitive changes in DLB due to its reliance on memory and language performance and its weakness in assessment of executive dysfunction. Alternative generic tests such as Dementia Rating Scale and Montreal Cognitive Assessment and PD-specific scales such as Parkinson Disease-Cognitive Rating Scale have shown higher sensitivity in PD and have been recommended for use in LBDs. Because of the frequent comorbidity of depression in DLB, screening for depression as an alternative cause or a contributor to cognitive impairment is recommended. Medications should be carefully reviewed, especially those with potential cognitive side effects, such as anticholinergic agents.

Psychiatric Symptoms

Detailed visual hallucinations (McKeith core clinical criterion) frequently occur in DLB. There is often overlap between visual hallucinations and other disorders of visual perception, including illusions, misidentification syndromes, and visual agnosias. Auditory, tactile, or gustatory hallucinations may also occur but are less common (McKeith supportive clinical criterion). In addition, complex and elaborate delusional beliefs can be seen early in the disease course (McKeith supportive clinical criterion). Several drugs used in the treatment of PD, including anticholinergic agents, dopaminergic agents, and amantadine can exacerbate psychotic symptoms. Depression, anxiety, and apathy (McKeith supportive clinical criteria) commonly occur in DLB and are closely associated with cognitive decline.

Parkinsonism

The core features of parkinsonism include rigidity, bradykinesia, and resting tremor. As a core clinical feature of DLB, only one of these three are required (as opposed to PD, where at least two are required). Resting tremor and asymmetry of symptoms are less common in DLB than in PD, especially in older individuals. Other common parkinsonian signs are hypophonic speech, masked facies, stooped posture, and shuffling gait.

During the neurologic examination, a careful search for extrapyramidal features should be performed, even when the patient does not endorse motor symptoms. The use of a standardized assessment, such as the Movement Disorder Society-United Parkinson's Disease Rating Scale, for parkinsonian features may be particularly useful for research purposes.

Sleep Disorders

The RBD (McKeith core clinical feature) is a highly specific marker of synucleinopathies, particularly DLB. The RBD often precedes, sometimes by decades, the onset of cognitive and motor symptoms (see "Prodromal Dementia With Lewy Bodies" section in the following text). Selective serotonin reuptake inhibitors diminish the diagnostic utility of RBD because these agents can cause RBD behaviors. In addition to RBD, other sleep disturbances commonly found in DLB include daytime hypersomnolence (McKeith supportive clinical criterion) and insomnia.

Autonomic Dysfunction

Dysautonomia is common early in the course of DLB and can even occur prior to the onset of cognitive or motor symptoms. Frequent manifestations include orthostatic hypotension, syncope, constipation, and urinary incontinence (McKeith supportive clinical criteria) as well as urinary retention and erectile dysfunction. These symptoms are sometimes severe enough to lead to diagnostic consideration of multiple system atrophy (MSA).

Fluctuating Attention and Concentration

Significant fluctuations in cognition are one of core clinical features of DLB. Patients may show episodic deficits in cognition that alternate with periods of normal or near-normal performance. Fluctuations may include both rapid (lasting minutes or hours) as well as slower (weekly or monthly) variations in alertness. As a result, changes in mental status and behavior may be seen within a single clinical interview as well as between consecutive examinations. Caregivers are the most reliable source of information regarding the presence of fluctuations.

DIAGNOSIS

Updated diagnostic criteria for DLB were recently put forth by the fourth report of the DLB consortium (Table 53.2) LEVEL 3.[1] Significant changes compared to the third report include elevation of rapid eye movement sleep behavior disorder (RBD) as a core clinical feature; lowering of neuroleptic sensitivity from a core to a supportive clinical feature; and creation of a biomarker category of criteria, with abnormal dopamine transporter imaging, cardiac sympathetic deinnervation, and polysomnographic demonstration of RBD as findings that can contribute to a diagnosis of probable DLB. The supportive clinical and biomarker features do not factor into the classification of probable or possible DLB but may prove useful to clinicians in bolstering a diagnosis of DLB.

The relative timing of the cognitive and motor symptoms is an important factor in diagnosing DLB. As stated earlier, the "1-year rule" posits that DLB is diagnosed when dementia predates or begins within 1 year of the onset of motor parkinsonian symptoms; if dementia starts more than 1 year after parkinsonism, then the diagnosis is PDD. This admittedly arbitrary cutoff, established by the first consensus DLB criteria, has been controversial, and some groups have advocated for its elimination. However, the revised McKeith guidelines supported its continued use.

The neuropathologic accuracy of these revised criteria has yet to be determined. The prior core criteria have high specificity but lower sensitivity (range 0%-85%, mean approximately 40%). In particular, the consensus criteria are more predictive for the rarer "pure" form of DLB rather than the more common findings of mixed DLB and AD pathology.

TABLE 53.2 Diagnostic Criteria for Dementia With Lewy Bodies[a]

Clinical Features	
Core	**Supportive**
• Fluctuations • Recurrent visual hallucinations, usually well-formed • REM sleep behavior disorder • Parkinsonism • At least one of bradykinesia, rigidity, or resting tremor	• Neuroleptic sensitivity • Postural instability, frequent falls • Recurrent syncope/transient unresponsiveness • Dysautonomia (constipation, orthostatic hypotension, urinary incontinence) • Hypersomnia • Hyposmia • Nonvisual hallucinations • Delusions • Apathy, depression, anxiety
Biomarkers	
Indicative	**Supportive**
• Abnormal DaTscan • Abnormal cardiac MIBG scan • Polysomnography showing REM sleep without atonia	• Lack of medial temporal atrophy on CT/MRI • Generalized reduced functional brain activity with reduced occipital activity (SPECT/PET) • Cingulate island sign • Posterior slowing on EEG
Diagnosis	
Probable DLB can be diagnosed when: • Two or more core clinical features are present. • One core clinical feature and one (or more) indicative biomarkers are present.	
Possible DLB can be diagnosed when: • One core clinical feature is present. • One (or more) indicative biomarker is present (without core clinical features).	

Abbreviations: CT, computed tomography; DLB, dementia with Lewy bodies; EEG, electroencephalography; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography; REM, rapid eye movement; SPECT, single-photon emission computed tomography.

[a]From McKeith IG, Boeve BF, Dickson DW, et al. Diagnosis and management of dementia with Lewy bodies: fourth consensus report of the DLB consortium. *Neurology*. 2017;89:88-100.

Prodromal Dementia With Lewy Bodies

Although a formal diagnosis of DLB requires the presence of dementia, there is great interest in identifying DLB patients at earlier stages of disease. Several studies have found that patients with nonamnestic MCI are more likely to develop DLB than AD. Cognitive symptoms predominate in this phenotype of prodromal DLB, but other patterns of prodromal DLB have been identified. These include prominent delirium and late-onset psychiatric disease, particularly psychosis and affective disorder. However, there are currently no formal criteria for prodromal DLB.

Another group at high risk for developing DLB are those with "idiopathic" RBD. The rate of conversion to a neurodegenerative synucleinopathy is very high, approaching 80% after 10 years of follow up. Of these, approximately half develop DLB, half develop PD, and a small percentage develop MSA. Even in those that develop PD, the presence of RBD confers an increased risk of developing cognitive impairment.

Diagnostic Testing and Evaluation

Laboratory workup is advised to exclude other potentially reversible causes of symptoms including infection, metabolic derangement, vitamin B_{12} deficiency or thyroid disease. Ancillary evaluations may include neuropsychological testing, neuroimaging, and cerebrospinal fluid (CSF) analysis.

Neuropsychological Testing

To most thoroughly assess for associated cognitive changes in DLB, formal neuropsychological testing is recommended. Although patients with DLB were more likely to have visuospatial and attentional deficits, AD patients were more likely to have significant impairment on memory testing, particularly memory encoding; the presence of prominent deficits on tests of executive function and problem solving, such as the Wisconsin Card Sorting Test, the Trail Making Test, and verbal fluency for categories and letters, may be useful clinical diagnostic indicators of DLB, as may pronounced impairment on tests of visuospatial performance such as block design, clock drawing, or figure copy tests. With the progression of dementia, the selectivity of this pattern for DLB versus AD may be lost. As a result, making an accurate differential diagnosis during the later stages of dementia using clinical presentation and neuropsychological testing alone becomes increasingly difficult because the cognitive deficits demonstrated in advanced DLB frequently overlap with those seen in AD. For such patients, functional neuroimaging may assist in diagnosis.

Neuroimaging

Structural Brain Imaging

Magnetic resonance imaging (MRI) of the brain without contrast or computed tomography if MRI cannot be done, should be obtained on patients without recent brain imaging to assess for

alternative structural abnormalities that may be contributing to or causing patients' complaints, including localized neoplasms, infections, strokes, or diffuse subcortical cerebrovascular disease. However, computed tomography or MRI as isolated studies has limited diagnostic utility. Generalized atrophy and white matter hyperintensities are nonspecific findings in dementia, and MRI may play a limited role in differentiating between types of dementia. Several studies indicate that coronal sections through the hippocampi usually show a greater degree of hippocampal atrophy in AD compared with DLB (McKeith supportive biomarker criterion). Despite the changes in the occipital lobe on functional imaging as described in the following text, regional occipital atrophy is generally not observed on MRI in DLB.

Dopamine Transporter Imaging

Ioflupane iodine 123 dopamine transporter single-photon emission computed tomography (SPECT) imaging (DaTscan) demonstrates reduced striatal dopaminergic activity in DLB (**Fig. 53.2A**). These findings are also seen in PD and atypical parkinsonisms but not in AD. A study in 326 patients with dementia reported a sensitivity of 78% and a specificity of 90% for DLB versus AD using DaTscan LEVEL 2.[2] A small study in autopsy-confirmed cases supports this robust discrimination. These results underlie the addition of abnormal dopamine transporter imaging as an indicative biomarker in the diagnosis of probable DLB.

FIGURE 53.2 Neuroimaging features of dementia with Lewy bodies (DLB). Characteristic neuroimaging findings in DLB, taken from a patient with pathologically confirmed DLB. **A:** DaTscan with adjacent axial sections showing nearly absent uptake in the putamen *(white arrows)* with relatively intact uptake in the caudate *(black arrows)*. **B:** Single-photon emission computed tomography scan showing cingulate island sign. The perfusion is reduced in the bilateral occipital cortices *(white arrows)*, with relative preservation in the cingulate cortex *(encircled with white dashed line)*. (Images courtesy of Lawrence Honig.)

Functional Brain Imaging

The DLB patients show decreased perfusion (technetium 99m labeled hexamethylpropylene amine oxime, ^{99m}Tc-HMPAO-SPECT) and metabolism (fluorodeoxyglucose positron emission tomography) in the lateral frontal, temporoparietal, and occipital lobes. The occipital lobe findings have potential diagnostic utility in distinguishing DLB from AD, with a sensitivity and specificity for SPECT of 65% and 87% and for PET of 90% and 80% (McKeith supportive biomarker criterion). The related cingulate island sign (**Fig. 53.2B**), showing preservation of posterior cingulate function relative to the occipital cortex, also shows promise in distinguishing DLB from AD, and may be useful in earlier, MCI-level stages of disease (McKeith supportive biomarker criterion).

Amyloid Imaging

The high frequency of concomitant AD pathology in DLB has prompted investigations in amyloid imaging. According to a recent meta-analysis, about 57% of DLB patients demonstrate positive amyloid imaging findings. By comparison, 35% of PDD patients have abnormal amyloid imaging. The anatomic pattern of amyloid tracer binding in DLB (and PDD) is very similar to that seen in AD, with preferential binding in the frontal lobes, posterior cingulate and precuneus, temporoparietal region and striatum.

Cerebrospinal Fluid Analysis

The CSF analysis can assist in the diagnosis of DLB. In particular, differentiating between AD and DLB can be aided by analysis of "AD biomarkers"—total τ, 181-phosphorylated τ (P-τ), and β-amyloid 1-42. The typical AD profile of elevated P-τ and reduced Abeta1-42 (often expressed as ATI, or Abeta1-42/tau index) is very sensitive for AD changes. Therefore, the absence of these changes can support a diagnosis of DLB in the correct clinical context. However, the specificity of the AD CSF profile is not as strong; this is likely to be especially so in the case of DLB, where (as discussed earlier) coexisting AD pathology is common. Indeed, one large series found that 22% of clinically diagnosed DLB patients had an AD CSF profile. Interestingly, only 9% of PDD subjects had an AD profile. One weakness of studies on CSF biomarkers in this area is the lack of data in pathologically confirmed cases.

A promising area is the analysis of markers of Lewy pathology in CSF. Many (although not all) studies have shown reduced levels of CSF total α-synuclein in DLB. The utility of this measure in distinguishing between DLB and AD is still unclear. Furthermore, other measures of aSyn that are more closely linked to Lewy pathology, such phosphorylated species, for example, phospho S-129 α-synuclein, or oligomeric α-synuclein, may prove more useful.

Autonomic Testing

Autonomic studies may be useful in distinguishing between DLB and AD. In particular, reduced cardiac sympathetic innervation, assessed by cardiac iodine 123 metaiodobenzylguanidine uptake, is an indicative biomarker criterion in the new McKeith guidelines. (It should be noted that cardiac metaiodobenzylguanidine scans are not approved for use in the evaluation of dementia in the United States.) Other assessments, such as tilt table testing and abnormal skin reflexes on sudomotor testing, may also be useful.

Differential Diagnosis

Alternative diagnostic considerations include AD (with coexisting parkinsonism or prominent psychiatric features), vascular dementia, and atypical parkinsonisms.

Although subtle extrapyramidal signs may be present in early stages of AD, notable parkinsonism typically does not develop until late-stage AD. The early appearance of cortical dysfunction, such as aphasia, or profound early memory loss usually suggests the presence of AD. Given that the pathologic changes of AD and DLB often occur together, it can be particularly difficult to clinically differentiate these diagnoses, particularly in later stages. In these cases, functional neuroimaging (eg, dopamine transporter imaging, amyloid imaging) may provide some indication of the underlying pathologic process(es).

Vascular disease may manifest as infarctions in multiple vascular territories or as microvascular/small vessel ischemic changes affecting periventricular and subcortical white matter, basal ganglia, and brainstem. These vascular changes can produce dementia and parkinsonism, which classically affects gait (lower body parkinsonism). A history of vascular risk factors, abrupt onset of symptoms with stepwise progression over time, focal neurologic signs, and evidence of diffuse vascular disease on neuroimaging suggest this alternate diagnosis.

The atypical parkinsonisms—progressive supranuclear palsy, MSA, and corticobasal degeneration—can sometimes present similarly to DLB. For example, MSA can cause RBD and dysautonomia, and progressive supranuclear palsy can present with early cognitive changes and postural instability. Other less common entities that may be included in the differential include depression, medication effects, prion disease, and delirium caused by metabolic or systemic disorders.

TREATMENT

The treatment of patients with DLB is clinically challenging and limited to symptomatic management. Because medications may be poorly tolerated, patient and caregiver education regarding risks, benefits, and limitations of treatment is important.

Cognitive Symptoms

The first step in the treatment of cognitive decline in patients with any DLB should be elimination of medications with detrimental cognitive effects, especially anticholinergic medications.

The rationale for the use of cholinesterase inhibitors is based on the widespread and severe cortical cholinergic deficits present in LBDs as well as their U.S. Food and Drug Administration (FDA) approval in AD. The cholinesterase inhibitor rivastigmine (4.6-13.3 mg/d by transdermal patch or 6-12 mg/d orally) is FDA approved for the symptomatic treatment of cognitive impairment in PDD LEVEL 1.[3] Although not FDA approved for the treatment of DLB, the use of rivastigmine is supported by meta-analysis as well as positive results in one double-blind randomized clinical trial. Importantly, rivastigmine treated participants improved on measures of apathy and anxiety and had fewer delusions and hallucinations. A phase 2 exploratory trial of donepezil (n = 140) showed it to be safe and well tolerated and showed improvement in both cognition and behavior. A phase 3 trial of donepezil (n = 120) did not yield positive results in the coprimary endpoints (MMSE and neuropsychiatric inventory [NPI-2]); however, the 10-mg dose showed significant improvement in MMSE. Donepezil was approved for treatment of DLB in Japan in 2014. There have been case reports of worsening cognitive function, rapid eye movement sleep disorder, or parkinsonism with cholinesterase inhibitors, so patients should be followed carefully while using these drugs. These medications also carry risk of gastrointestinal side effects including nausea, vomiting, or diarrhea, although risk appears to be minimized through transdermal delivery. If cholinesterase inhibitors are discontinued, they should be tapered as opposed to abruptly stopped in order to minimize risk of sudden cognitive and behavioral worsening. Overall, the use of cholinesterase inhibitors (specifically rivastigmine and donepezil) as first-line treatment of both cognitive and neuropsychiatric symptoms is recommended by the revised McKeith consensus criteria.

Animal models of parkinsonism demonstrate glutamatergic overactivity in the striatum, and memantine, an *N*-methyl-D-aspartate receptor antagonist, has been FDA approved for moderate to severe AD. Studies of the effects of memantine (10 mg orally twice per day) have been inconsistent. The two largest randomized controlled trials combined both PDD and DLB. The first (n = 72 combined; 32 with DLB) showed improvement in clinical global impression of change in the DLB group only over 24 weeks. The second trial of memantine (N = 199, with 75 DLB) demonstrated improvement in NPI-2 only in the DLB group. Neither study showed improvement in cognition. Other studies have noted that memantine may worsen delusions and hallucinations in patients with DLB.

Several clinical trials are testing novel approaches to the treatment of cognitive deficits in LBDs. Selective targeting of serotonin receptor subtypes is a promising approach for cognitive dysfunction. However, recent failed trials have included targeted antagonism of serotonin 5-HT6 and/or serotonin 5-HT2A (5-HT2A), inhibition of phosphodiesterase 9, D1 receptor activation, glutamatergic inhibition, and stabilization of glucocerebrosidase. Several nonpharmacologic interventions are also promising. A small trial of bilateral deep brain stimulation of the nucleus basalis of Meynert in patients with PDD is underway. In patients with PD-MCI, noninvasive stimulation, with either repetitive transcranial magnetic stimulation or transcranial direct current stimulation, led to improvement in cognitive measures. Finally, exercise in nondemented PD patients improved working memory and attention.

Motor Symptoms

Parkinsonian motor symptoms in DLB are treated similarly because they are in PD. Generally speaking, patients with DLB appear to be less responsive to dopaminergic therapy than those with PD or PDD. Patients with DLB may be particularly susceptible to the neuropsychiatric side effects of dopaminergic medications, which may limit dosage level or require concomitant use of antipsychotic agents. Levodopa likely provides the best risk-benefit profile in DLB patients. Most adjunctive medications (eg, monoamine oxidase-B inhibitors, catechol-O-methyltransferase inhibitors) do not provide enough motor benefit to warrant their potential side effects. In particular, anticholinergic agents and amantadine frequently worsen cognitive impairment and psychosis and should be used with caution. Similarly, dopamine agonists should also be avoided due to potential for worsening psychosis and sedation. Patients with DLB are generally excluded from consideration for deep brain stimulation therapy due to poor outcome. Interestingly, zonisamide, an anticonvulsant that also inhibits release of glutamate, was studied as adjunctive treatment along with levodopa in DLB patients in a phase 2 trial. After 12 weeks, the higher dose (50 mg) led to a

modest motor benefit, without worsening cognitive or psychiatric symptoms.

Often overlooked are nonpharmacologic measures that can play an important role in the management of motor symptoms. Given patients' risk of falls and fluctuations in alertness, clinicians should encourage caregivers, with assistance from ancillary services, to take preventative steps to improve safety in the home environment. Multidisciplinary care, incorporating physical, occupational, and speech therapy, can provide significant improvement in several areas of motor function.

Psychosis

Passive observation of visual hallucinations and delusions can be considered if these symptoms are not causing significant disruption. Elimination or reduction of medications, especially anticholinergics that can exacerbate psychosis should be attempted first. Consideration should also be given to lowering the dosage of dopaminergic medications if possible.

If treatment is needed, typical and most atypical antipsychotics should be avoided in DLB patients because they are particularly sensitive to dopamine receptor blockers. It is estimated that almost 60% of patients with DLB may exhibit exaggerated extrapyramidal signs, sedation, immobility, or neuroleptic malignant syndrome with fever, generalized rigidity, and muscle breakdown following exposure to neuroleptics. Among the atypical antipsychotic agents, clozapine has the best established utility, although most of the studies have been performed in PDD patients LEVEL 1 .[4] Clozapine has an extremely low risk of exacerbating parkinsonism; however, it has a risk of agranulocytosis and requires close monitoring of white blood cell count. Low-dose quetiapine (25-100 mg) is considered effective (despite negative results from a single placebo-controlled trial in DLB). Common side effects include sedation and orthostatic hypotension; furthermore, patients and caregivers must be educated about its association with increased risk of cardiac morbidity, mortality, and stroke in elderly patients with dementia. Finally, as discussed earlier, cholinesterase inhibitors improve psychotic symptoms in patients with LBD patients and can be considered as a first-line approach.

Pimavanserin, a selective 5-HT2A inverse agonist, was approved in the United States for treating hallucinations and delusions in PD psychosis. It has not been studied in PDD or DLB; in fact, patients with dementia were excluded from the pivotal phase 3 trial in PD psychosis. Interestingly, post hoc analysis of this study found that patients with poorer cognitive function (MMSE 21-24) benefited equally from pimavanserin as compared with subjects with MMSE >24. There is an ongoing study of pimavanserin in psychosis associated with all-cause dementia.

Other Features

Additional common features of DLB include mood and sleep disorders as well as dysautonomia. These disorders are covered separately in Chapter 86 and are briefly covered here in the context of DLB. Evidence is lacking regarding the treatment of many of these conditions in DLB, and recommendations are often adapted from PD and other neurodegenerative cognitive disorders including AD.

Mood Disorders

Monoamine reuptake inhibitors—including selective serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors—may be effective in treating anxiety and depression in patients with DLB. However, more research needs to be performed on the safety of these medications in these patient populations. There have been no randomized controlled trials in DLB for depression or anxiety. Electroconvulsive therapy has been successfully used to treat depression, but electroconvulsive therapy is infrequently used in dementia out of concern for worsening cognitive impairment related to treatment. Moreover, most studies have explored its use in early stage dementia. Benzodiazepines should be avoided (except for RBD), especially for long-term use, because of the potential for worsening confusion, gait disorder, and paradoxical agitation. Tricyclic antidepressants should be avoided due to their anticholinergic effects. Finally, psychotherapy may also be effective, especially in milder patients.

Sleep

Insomnia is a common problem in LBD. Usually, patients have trouble with sleep maintenance, rather than initiation. Proper sleep hygiene is important in optimizing the sleep-wake cycle. Maintaining a daily routine, exposure to natural light during the daytime hours, eliminating daytime naps, and elimination of late-day caffeine consumption are important recommendations. If pharmacologic treatment is needed, several options are available, including (starting with the most benign) melatonin, mirtazapine, trazodone. Sedatives, such as zolpidem, should be used with extreme caution because they can exacerbate neuropsychiatric symptoms. The antipsychotic quetiapine can also be used given its soporific effects, but should be used with caution, related to its adverse effect profile described earlier (see "Psychosis" section).

The RBD, if present, often does not require treatment if it is infrequent and does not lead to injury. Clonazepam (0.25-1 mg orally before bed) or melatonin (3 mg orally before bed) can be used to effectively treat symptoms. Nonpharmacologic treatments may include separate bed for partner, the placement of the mattress on the floor, or placing the mattress against the wall in conjunction with a bedrail on the opposite site, padding the corners of nearby furniture, removing potentially dangerous objects from the bedroom, and bed alarms alerting others if the patient has no bed partner.

Dysautonomia

Nonpharmacologic treatment of orthostatic hypotension includes use of compression stockings, ensuring adequate hydration, use of salt tablets. Pharmacologic options include fludrocortisone, pyridostigmine, midodrine, and droxidopa, either alone or in combination. Constipation can often be successfully addressed with dietary changes and adequate hydration. Nonprescription options, such as docusate sodium, senna, or polyethylene glycol, are also effective.

Lifestyle

It is important to discuss management of finances and medications with patients and caregivers. Cognitive impairment and parkinsonism associated with DLB place patients at higher risk for driving impairment. A formal driving evaluation should be considered in patients with DLB who wish to continue driving.

Future Directions

No clinical trials published to date have investigated disease-modifying agents in DLB. Future clinical trial investigations in DLB may include stimulation of endogenous neurotrophic factors, reduction of α-synuclein aggregation, immune-modulating therapies, and inflammatory inhibitors.

OUTCOME

There is no cure or disease-modifying therapy for DLB. Psychotic symptoms, particularly visual hallucinations, persist over time. Parkinsonism also worsens over time, especially in patients for whom this is an early symptom. Relative to AD, DLB has a more aggressive course. A recent meta-analysis found that survival time in DLB was 4.1 years from diagnosis, versus 5.7 years for AD. Other studies have found that patients with DLB progress to institutionalization earlier than patients with other types of dementia, perhaps due to earlier development of parkinsonism and daytime somnolence. Survival after nursing home placement is significantly impacted by the presence of depression and parkinsonism, including rigidity and gait abnormalities.

54 Vascular Dementia and Cognitive Impairment

Nikolaos Scarmeas and Adam M. Brickman

KEY POINTS

1. Vascular dementia is characterized by cognitive dysfunction with accompanying functional decline caused by either ischemic or hemorrhagic cerebrovascular disease, or sequelae of hypoperfusion, hypotension, or hypoxia.
2. Cerebrovascular disease can contribute to dementia syndromes even if not the primary biologic etiology of dementia, or can be the primary cause of dementia.
3. A diagnosis of vascular dementia requires (1) clinically and radiologically ascertained strokes, (2) dementia, and (3) a clear temporal (presumably causal) relationship between stroke(s) and dementia.
4. As many as 15% to 20% of patients with acute ischemic stroke older than age 60 years have dementia at the time of the stroke, and 5% per year develop dementia thereafter.
5. The majority of older adults with dementia harbor mixed Alzheimer and vascular neuropathologic changes.
6. Patients with vascular dementia often experience a stepwise cognitive decline resulting from additional cerebrovascular events.
7. Primary prevention of stroke via control of related risk factors may reduce vascular dementia rates.

INTRODUCTION

During much of the 20th century, it was assumed that most dementia of the elderly was vascular in origin, an assumption challenged during the last few decades after the recognition of the importance of Alzheimer pathologic changes. Nevertheless, interest in the role of cerebrovascular disease on cognition and function reemerged particularly not only due to wider use of modern neuroimaging techniques but also due to accumulation of more knowledge on the impact of small-vessel cerebrovascular pathology. The traditional concepts that blood vessel blockage and leakage are primary causes of cognitive impairment through their impact on neuronal cell loss is being gradually enriched by deeper understanding of the role of the neurovascular unit, which includes the interaction of endothelial cells and pericytes with astrocytes, oligodendrocytes, and microglia (**Fig. 54.1**). Overall, the clinical importance of vascular abnormalities in cognitive performance has been a focus of increased attention.

Brain injury caused by ischemic or hemorrhagic lesions, ischemic white matter disease, and sequelae of hypotension or hypoxia, can undoubtedly contribute to cognitive impairment. Vascular dementia can be characterized generally as cognitive dysfunction attributable to vascular brain injury that affects functional abilities, such as instrumental and basic activities of daily living. It can result from a variety of mechanisms (**Table 54.1** and **Figs. 54.2** to **54.3**).

Although several diagnostic schemes for vascular dementia have been proposed, there is no current consensus. Available clinical criteria have been somewhat controversial and many have not been adequately validated, have been inconsistently applied, and lack satisfactorily high sensitivity and specificity. *Overall, as a practical rule, a diagnosis of vascular dementia requires (1) clinically (symptoms-signs) and radiologically confirmed strokes, (2) dementia, and (3) a clear temporal relationship between stroke(s) and dementia.* Cerebrovascular disease is itself heterogeneous, with a variety of pathophysiologic mechanisms and clinical manifestations and correspondingly, vascular dementia manifests as a heterogeneous clinical syndrome.

Cerebrovascular disease can cause cognitive impairment in the absence of dementia. There is also a growing appreciation that most cases of dementia are characterized by mixed pathologies, including cerebrovascular disease in addition to neurodegenerative, and that cerebrovascular disease can contribute to cognitive dysfunction even if it is not considered the primary cause of dementia. Because of these factors, the term *vascular cognitive impairment* was introduced to recognize the continuum of the contributions of cerebrovascular disease—across multiple subtypes—to cognitive functioning, which ranges from subtle effects on cognition, to a secondary or comorbid contributor to dementia, to the primary etiology of dementia. Cerebrovascular disease can be focal or distributed across multiple brain systems; the cognitive manifestations of vascular cognitive impairment is equally heterogeneous.

EPIDEMIOLOGY

As many as 15% to 20% of patients with acute ischemic stroke older than age 60 years have dementia at the time of the stroke, and 5% per year develop dementia thereafter. On a clinical basis, vascular dementia has been long considered the second (after Alzheimer disease) or third (after Alzheimer and dementia with Lewy bodies) most frequent cause of dementia. Considering data from pathologic series and related clinical-pathologic correlations highlights the complexity of the issue, particularly because most cases of dementia are of mixed etiology. Although most elderly patients with dementia have Alzheimer type pathologic changes (70%-80%), the vast majority of them have coexisting

FIGURE 54.1 Key constituents of the neurovascular unit and possible entry points for disease mechanisms in cerebral small-vessel disease. Arterioles penetrate the brain and branch into capillaries. They are each surrounded by a perivascular space that is connected to the cerebrospinal fluid. Capillary endothelial cells, including their connecting tight junctions, a specialized basement membrane, pericytes, and astrocyte end-feet collectively form the blood-brain barrier. The blood-brain barrier is essential for maintaining the interstitial milieu. Astrocytes maintain the interstitial fluid balance, provide energy to neurons, and relay signals between neurons and other cells to the vasculature to adapt blood flow to energy demand. Oligodendrocytes form and repair myelin around axons to which they also provide metabolic and trophic support. At the cellular level, endothelial cell dysfunction and blood-brain barrier dysfunction increase interstitial fluid and proteins, disrupt astrocyte end-feet, which impairs interstitial fluid exchange, block oligodendrocyte precursor cell maturation, which impairs myelination and repair and energy support to axons, and impede normal astrocyte function, decreasing neuronal energy supply. Several of the cellular and functional constituents of the vasculo-glio-neuronal unit (ie, endothelial cells, pericytes, astrocytes, oligodendrocytes, neurons, and the extracellular matrix) represent possible entry points for disease mechanisms in small-vessel disease. (Obtained from Wardlaw JM, Smith C, Dichgans M. Small vessel disease: mechanisms and clinical implications. *Lancet Neurol.* 2019;18(7):684-696.)

cerebrovascular disease, whereas fewer than 30% have "pure," Alzheimer-only, pathology. Similarly, most older adults have some degree of small-vessel cerebrovascular pathology, but a large amount of small-vessel dysfunction may be necessary to be the sole cause of dementia. Dementia due to infarcts solely without significant pathologic contributions of Alzheimer or Lewy body pathology is strikingly uncommon, with estimated rates between 2% and 10% of dementia cases.

Ethnic and geographic variability of vascular cognitive impairment and dementia rates have been reported. Vascular dementia prevalence in developing countries seems to be low, whereas rates seem to be relatively higher in many Latin American and Asian countries, including China. Adding to the argument of higher contribution rates of vascular cognitive impairment as contributory to dementia but perhaps less frequently the sole cause is the fact that most pathologic studies consider only larger infarcts, whereas microinfarcts are extremely common and diffuse in the brain, although the clinical importance of such microinfarcts is not fully established. Finally, many white matter abnormalities visualized on brain magnetic resonance imaging are often undetectable by standard neuropathologic examinations performed upon autopsy, suggesting limited sensitivity of neuropathology for detection of cerebrovascular damage.

PATHOBIOLOGY

Overall, strokes themselves and factors that predispose to cerebrovascular disease are considered risk factors for vascular dementia and vascular cognitive impairment. Predisposing conditions for cerebral infarcts or hemorrhages are numerous and should be included in patients' workups (see Chapter 45, Primary and Secondary Stroke Prevention). Patients with vascular dementia are usually old and may suffer from cardiovascular

TABLE 54.1 Proposed Types of Vascular Dementia Based on Localization and Pathophysiologic Mechanism

Vascular Dementia Subtype	Comments/Additional Information for Each Subtype, Including Localization, Mechanisms, etc
Critically located (strategic "single") infarcts	Bilateral frontal infarctions from anterior cerebral artery occlusions Bilateral thalamic infarction from posterior cerebral artery occlusions Inferior medial temporal lobe infarcts Middle cerebral artery occlusions leading to frontal/parietal infarcts, etc
Multiple ischemic infarcts affecting large vessels	Not necessarily in critical locations but leading to significant parenchymal volume loss
Small-vessel disease	Multiple lacunar infarcts in the basal ganglia Multiple lacunar infarcts in subcortical or periventricular white matter leading to a more widespread, patchy pattern often described as leukoaraiosis in brain imaging studies—previously called *Binswager disease*
Hemorrhagic infarcts	Intraparenchymal hemorrhages due to chronic vascular damage from hypertension Amyloid angiopathy Intracerebral or subdural hematomas or subarachnoid hemorrhage
Hypoperfusion	Due to internal carotid artery stenosis; due to (or sometimes in combination with) systemic causes such as heart failure, hypotension, bypass surgery, cardiac arrest, medications, or other systemic conditions
Other mechanisms	Combinations of the above Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), an autosomal dominant form of cerebrovascular dementia (and also migraines and psychiatric symptoms) related to mutations in the *NOTCH3* gene on chromosome 19 Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS)

FIGURE 54.2 Fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) findings in some vascular dementia subtypes. **A:** FLAIR MRI demonstrating a large-vessel middle cerebral artery infarct involving the angular gyrus. **B:** Binswanger disease, with extensive symmetric ischemic leukopathy. **C:** Bilateral watershed infarcts from hypoperfusion after cardiac arrest. **D:** Strategic infarct dementia resulting from bilateral thalamic infarcts. (Figs. **A-C** are reproduced with permission from Guermazi A, Miaux Y, Rovira-Cañellas A, et al. Neuroradiological findings in vascular dementia. *Neuroradiology* 2007;49[1]:1-22.)

FIGURE 54.3 Schematic diagram illustrating the three most commonly observed cerebrovascular diseases and their resulting cerebrovascular lesions that may lead to specific types of vascular dementia. (Obtained from McAleese KE, Alafuzoff I, Charidimou A, et al. Post-mortem assessment in vascular dementia: advances and aspirations. *BMC Med*. 2016;14[1]:129.)

disease, including heart attacks, cardiac arrhythmias, and congestive heart failure, or from diabetes, hypertension, and dyslipidemia, with eventual damage in many organs. Cerebral amyloid angiopathy is among the most common causes of hemorrhagic lesions that are typically in lobar regions; small hemorrhagic lesions in subcortical areas are more commonly attributable to hypertensive vasculopathy. Cerebral amyloid angiopathy is characterized by amyloid β peptide deposits within small to medium-sized blood vessels of the brain and leptomeninges. It can present with or without coexisting Alzheimer disease neuropathologic changes. Beyond genetic susceptibility to strokes, rare genetic causes of vascular dementia include cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) and mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes.

Whether Alzheimer type pathologic changes induce cerebrovascular damage or whether cerebrovascular disease promote Alzheimer neuropathology is not settled. Overall, there is a complex interaction among stroke, vascular risk factors, and Alzheimer disease, although the exact nature of this interaction remains unknown.

DIAGNOSIS

In contrast to mild cognitive impairment or dementia due to underlying Alzheimer disease that predominantly affects memory, vascular cognitive impairment, and vascular dementia may have more variable effects on cognitive domains (with or without memory). The symptoms and signs of vascular dementia or vascular cognitive impairment may include difficulty with acquiring and remembering new information, impaired reasoning, judgment and handling of complex tasks, deficits in visual spatial abilities, problems with language function (comprehension, expression, etc), and changes in personality or behavior. The exact mix of the above abilities depends on cerebral localization of vascular damage or the brain systems affected by cerebrovascular disease. If for example, the temporal lobe neural circuits responsible for memory function are less affected, amnesic deficits, a key feature in Alzheimer disease, may be less prominent in vascular dementia. Focal noncognitive deficits related to vascular dementia causing strokes may also coexist.

A more "cortical" syndrome with clear stepwise deterioration including focal motor or sensory symptoms and signs, aphasia, neglect, abulia, apraxia, agnosia, amnesia, etc, resulting from repeated distinct strokes may be present. However, vascular dementia often presents as a more "subcortical" syndrome that is characterized by apathy, inertia, bradyphrenia, deficits in attention and concentration, executive dysfunction (problems with organization, planning, and strategy), often abnormal gait (which may mimic apraxic or magnetic gait or that of lower body parkinsonism), urinary urgency or incontinence, depression, as well as emotional incontinence ("pseudobulbar affect"), including inappropriate crying or laughing.

In general, in the differential diagnosis from Alzheimer disease, features that would favor the diagnosis of vascular dementia would include an abrupt onset of dementia temporally related to a cerebral infarct, a stepwise deterioration, and a fluctuating course. There are no diagnostic tests specific for vascular dementia.

Clinical presence of stroke documented by either history (symptoms) or neurologic examination (residual signs), although not entirely required, enhances specificity of vascular dementia diagnosis.

Presence of infarcts in brain imaging studies is a requirement for a diagnosis of vascular dementia. Their nature (hemorrhagic, ischemic), size (small, large), number (one strategic, many), or location (cortical, subcortical, different brain structures) can widely vary (Fig. 54.2). Widespread, confluent white matter disease or hyperintensities, often referred to leukoaraiosis, can be a prominent feature and may be an indicator of vascular cognitive impairment even in the absence of frank infarct.

Evaluation to define a specific stroke subtype and etiology should be included in a diagnostic workup. In nonadvanced stages, cognitive deficits should be documented with neuropsychological evaluation, but their nature is also nonspecific because

TABLE 54.2 Medications Commonly Prescribed for Vascular Dementia

Medication — Active Substance	Route	Targeted Maximum Daily Dose	Frequency of Administration
Donepezil	Oral	10 mg	Once a day
Rivastigmine	Oral	12 mg	6 mg twice a day
Rivastigmine	Transdermal	13.3 mg	Once a day
Galantamine	Oral	24 mg	Once a day
Memantine (immediate release)	Oral	20 mg	10 mg twice a day
Memantine (extended release)	Oral	28 mg	Once a day

they depend on stroke localization that may vary from patient to patient. However, deficits in frontal function, including difficulties with attention-concentration, slow speed of processing, difficulties with initiation, and executive dysfunction may be prominent. Particularly, in subcortical forms of vascular dementia, amnestic deficits may be characterized by difficulties in free recall of information with relative improvement in recognition (ie, when aided with various strategy cues).

MANAGEMENT

Prevention and Treatment of Stroke

Primary prevention of stroke treatment, treatment of recent stroke, and prevention of recurrent stroke are central to vascular dementia rates, course, and prognosis. Smoking cessation, control/treatment of hypertension, diabetes, dyslipidemia, obesity, asymptomatic carotid endarterectomy, etc are examples of preventive strategies. Similarly, antiplatelets, anticoagulants, and symptomatic carotid endarterectomy are examples of stroke recurrence prevention approaches. Stroke treatment and stroke preventative strategies are discussed in more detail in Chapters 36 and 45.

Cognitive and Behavioral Symptoms

The efficacy of cholinesterase inhibitors and memantine, approved therapies for Alzheimer dementia have not been extensively studied in populations where dementia is considered to be only due to vascular origin. At the same time, efficacy of these medications—medication classes has been demonstrated in patients with mixed Alzheimer dementia and stroke/vascular dementia LEVEL 1.[1-11] Given that such mixed dementia is quite common and that it is clinically often difficult to rule out concomitant Alzheimer pathologic changes in patients diagnosed with vascular dementia, it stands to reason to offer cholinesterase inhibitors and memantine therapy to such patients. Initiation with one of the three approved cholinesterase inhibitors, subsequently followed by addition of memantine is the common practice. The doses commonly prescribed and corresponding titration schedules toward the maximum dose (occurring during the course of weeks/months depending on the particular medication) are those used for Alzheimer dementia, the primary indication for such treatments (Table 54.2). The treatment approaches to behavioral and neuropsychiatric symptoms of dementia are similar to those taken in Alzheimer disease and related dementias as discussed elsewhere in this section.

OUTCOME

Prognosis in vascular dementia is more variable than that of Alzheimer disease because it is largely dependent on coexisting strokes. Providing effective modification of cerebrovascular disease risk factors occurs, none or only a limited number of future strokes may occur, and the cognitive deficits can remain relatively static for protracted periods or until death. For other vascular dementia patients who continue to suffer from additional cerebral infarcts, a progressive cognitive decline and dementia deterioration is usually noted.

Prion Diseases 55

Boon Lead Tee and Michael Geschwind

KEY POINTS

1. Prion diseases are a group of neurodegenerative disorders caused by misfolding of the prion-related protein into the pathologic form commonly known as *prions*.
2. Human prion diseases can occur in three ways: sporadic (most common), genetic mutations in the prion protein gene, and acquired cases (rare).
3. Sporadic Creutzfeldt-Jakob disease (CJD) typically begins in the seventh decade with rapid onset and progression of several cognitive, motor, and behavioral changes; visual disturbances and constitutional symptoms also are common.
4. Many of the cerebrospinal fluid biomarkers used for sporadic CJD diagnosis reflect rapid brain cell injury and are not as specific as real-time quaking-induced conversion assay.
5. Brain magnetic resonance imaging changes in sporadic CJD include cortical gyral and/or deep nuclei hyperintensities on fluid-attenuated inversion recovery and especially diffusion-weighted imaging sequences.
6. A negative family history does not exclude the possibility of a genetic prion disease.
7. Most prion protein gene missense mutations have near 100% penetrance.
8. Genetic testing panels for autosomal dominant dementias and/or next-generation sequencing may miss less common prion protein octapeptide insertions and other insertions/deletions.

INTRODUCTION

Prion diseases represent a group of fatal and transmissible neurodegenerative disorders. They are caused by the conversion of the prion-related protein (PrP^C, in which C stands for the normal cellular form of the protein) into the misfolded pathologic form of PrP commonly known as *prions* or PrP^{Sc} (Sc stands for scrapie, the prion disease of sheep and goats). The term *prion* stemmed from the term *proteinaceous infectious particle*. Prions were discovered by Stanley B. Prusiner in 1982 who was subsequently awarded the Nobel Prize in Physiology or Medicine in 1997. Prior to this, prion diseases were thought to be caused by "slow viruses" with long incubation period between exposure and disease onset. The ground-breaking discovery of the prion protein, and its mechanism for causing disease by misfolding, expanded the scientific understandings of infectious diseases that traditionally regarded the presence of nucleic acids (ie, DNA or RNA) as mandatory in infectious agents. Studies have not only proven that the prion protein is necessary for the development of prion diseases, but researchers also have identified the self-templating and self-propagating nature of prions, with the latter being a common feature of other neurodegenerative diseases. The discovery of the human prion protein gene, *PRNP*, that encodes human PrP and that mutations in *PRNP* lead to genetic prion disease (gPrD) further strengthened the prion hypothesis.

History and Nomenclature

The first prion disease was described more than 150 years ago in animals, sheep and goats, and was named scrapie because the infected animals developed itching and scraped themselves against objects for relief. As a result, the pathologic form of prion protein often is referred to as PrP^{Sc}. Other terms also are used in the literature to refer to prions, such as PrP^{Res}, in which Res refers to the transmissible core of prions that is resistant to protease digestion. The resemblance of the animal prion disease scrapie to the acquired human prion disease Kuru, and with sporadic human prion disease (sporadic Creutzfeldt-Jakob disease or sCJD), was first highlighted in 1959. At the time, all were thought to be caused by a "slow virus." In 1920, the German neurologist Hans Gerhard Creutzfeldt reported a 23-year-old woman with spastic paraparesis, status epilepticus, dystonia, and cerebellar ataxia. Between 1921 and 1923, another German neurologist, Alfons Maria Jakob, described five cases that he thought were similar to Creutzfeldt's case. In retrospect, Jakob's cases were clinically different from Creutzfeldt's case, and in review of the clinical presentation and pathology, Creutzfeldt's case was not prion disease and only two, or possibly three, of Jakob's cases had what we would now consider prion disease clinically and/or pathologically. For decades, the disease was called *Jakob disease*, *Creutzfeldt disease*, or *Jakob-Creutzfeldt disease* or *syndrome*. In the 1960s, however, a prominent researcher in the field, Clarence J. Gibbs, began to use the term *CJD* because he liked having the initials closer to his own. Thus, some researchers consider that the most accurate terminology for human prion disease should be Jakob disease or possibly Jakob-Creutzfeldt disease. The abbreviation for Jakob-Creutzfeldt disease, however, has caused some clinicians to confuse it with the John Cunningham (JC) virus that causes progressive multifocal leukoencephalopathy. For this reason and because the term *CJD* has become so common, we use this ubiquitous, albeit historically inaccurate, terminology in this chapter.

Prior to the discovery of the prion, prion diseases were referred to as *transmissible spongiform encephalopathies* (TSEs) given the transmissibility of the diseases and the spongiform pattern (actually vacuolation) commonly found on neuropathology. In view that some prion diseases have not been shown to be transmissible and not all prion diseases show spongiform pathologic changes, the term *TSE* is somewhat antiquated, and therefore we do not use it as a general term to describe prion diseases in this chapter.

TABLE 55.1 Prion Disease Classification

Category	Name of Disorder or Syndrome	Abbreviation	Subtypes/Comments
Sporadic	Sporadic Creutzfeldt-Jakob disease	sCJD	At least six different subtypes or "molecular classification" based on *PRNP* codon 129 polymorphism and prion typing
	Sporadic fatal insomnia	sFI	The MM2thalamic subtype of sCJD, which clinically presents similarly to FFI
	Variable protease-sensitive prionopathy	VPSPr	Very rare sporadic disease with most of PrP^{Sc} being sensitive to protease digestion; fewer than 20 cases reported
Genetic	Familial CJD	fCJD	More than 20 missense mutations and some OPRIs
	Gerstmann-Sträussler-Scheinker syndrome	GSS	More than a dozen missense mutations and some OPRIs
	Fatal familial insomnia	FFI	Due to a single *PRNP* missense mutation, D178N, usually with codon 129M
	Octapeptide repeat insertions	OPRIs	Named based on the number of OPRIs; typically depending on size of OPRI, can present as fCJD, GSS, or along the spectrum of the two.
	Stop codon mutations	—	Highly variable, atypical clinical features for most PrDs, and pathology findings reveal brain amyloid plaques and/or prion amyloid angiopathy.
Acquired	Variant CJD	vCJD	From consumption of bovine spongiform encephalopathy or exposure to vCJD prions in blood
	Kuru	Kuru	—
	Iatrogenic CJD	iCJD	Human pituitary hormones, dura mater grafts and corneal transplants, reused depth electrodes

Abbreviations: PrDs, prion diseases; PrP^{Sc}, scrapie isoform of the prion protein.

Human prion diseases can occur in three ways: sporadic (spontaneous), genetic (familial, inherited), and acquired (transmitted, infectious) (Table 55.1). Approximately 85% of human prion diseases cases occur spontaneously, 15% are genetic (due to autosomal dominant mutations in *PRNP*), and fewer than 1% are acquired cases. The sporadic form of prion disease is referred to as *sCJD* because it is believed to occur through the spontaneous misfolding of normal form of the prion protein, PrP^{C}, into the pathologic misfolded form, PrP^{Sc}. Based on their clinical and pathologic features, gPrDs have been historically categorized into three different forms: familial CJD (fCJD), Gerstmann-Sträussler-Scheinker disease (GSS), and fatal familial insomnia (FFI). This classification, however, is antiquated because it developed prior to the discovery of *PRNP* and thus fails to encompass the variability within certain mutations as well as the clinical and pathologic phenotypes of some *PRNP* mutations, such as stop codons and octapeptide repeat insertions (OPRIs). Despite being the least common form of human prion diseases, the acquired forms of CJD (including Kuru, variant CJD [vCJD], and iatrogenic CJD [iCJD]) have received much attention due to their inadvertent transmission from animals to humans and from human to human. Human prion diseases generally are considered as the prototypical rapidly progressive dementia (RPD), although not all forms, particularly of some genetic mutations, progress rapidly.

PATHOBIOLOGY

Prion Protein Properties

Both PrP^{C} and PrP^{Sc} share identical amino acid sequences (with the exception of gPrDs) but differ in their three-dimensional conformational structures. PrP^{C} is comprised predominantly of α-helical structure, whereas PrP^{Sc} is comprised primarily of β-sheet structure that is likely stacked in a solenoid manner. Proteins rich in β-sheet structure are usually found to be highly resistant to proteolysis and thermodynamically stable. PrP^{Sc} also possesses a self-templating property in which PrP^{Sc} can act as a template and convert PrP^{C} into the misfolded conformation, PrP^{Sc}, when they come into contact with each other; this conversion process becomes exponential. Furthermore, different strains of PrP^{Sc} exist that vary in terms of their biologic and physicochemical properties. Such strain diversity partially explains the variabilities in tissue tropism, host affinity, and clinical presentations of different prion diseases.

Animal studies have shown that the presence of PrP^{C} is compulsory for prion pathogenicity; $PrP^{-/-}$ (knockout) transgenic mice can neither be infected with prions nor replicate prions in their tissues. When $PrP^{-/-}$ transgenic mice are transplanted with neuronal tissue expressing PrP^{C} and the mice are infected with prions, only this explanted tissue has PrP^{Sc} accumulation, whereas the host brain tissue remains devoid of PrP^{Sc}.

Prion Protein Functions

The human prion protein gene, *PRNP*, is located on the short arm of chromosome 20 and is highly evolutionarily conserved. Its normal form protein, PrP^{C}, is speculated to be related to neuronal development and function, although the exact functions remain largely unknown. Scientists have attempted to investigate the functions of PrP^{C} by analyzing the phenotypes of mice with their prion protein gene, *PRNP*, knocked out. Unfortunately, numerous reported traits were found not to be reproducible in *PRNP* knockout mice of different genetic backgrounds. This raised concerns that some of the reported traits were caused by the Mendelian segregations of *PRNP*-flanking genes in mice with mixed genetic background. Thus, studying the phenotypes

of *PRNP* knockout mice with pure genetic background may better represent PrP^C protein functions. *PRNP* knockout mice with pure genetic background have been found to develop chronic demyelinating peripheral neuropathy, altered circadian rhythm, and altered synaptic plasticity. Such findings suggest that PrP^C protein may play a role in sustaining myelin integrity, maintaining circadian rhythm, and facilitating synaptic plasticity. Furthermore, if *PRNP* is only knocked out after mice have fully developed, mice remain largely phenotypically normal, suggesting that PrP^C may be more essential during development.

Prion Protein Pathogenicity

Prion disease is generally believed to be more of a gain of function than a loss of function disease primarily for two reasons: (1) Homozygous or hemizygous *PRNP* knockout mice (the latter with half the level of PrP^C) remain largely asymptomatic, and (2) prion protein expression level is directly associated with the rate of disease progression in mice models. Some studies suggest that the pathogenicity of prion protein may be associated with its proteolytic processing. Mice in a high-stress environment seem to favor the β-cleavage over α-cleavage proteolytic processing, which generates membrane-bound C terminal protein (C2) that possess a amyloidogenic core that may in turn facilitate prion aggregation. Furthermore, the glycosylphosphatidylinositol anchor that attaches PrP^C onto the cell membrane may be involved in the pathophysiology of prion protein. Evidence supporting this is that transgenic mice which encode PrP^C without its glycosylphosphatidylinositol anchor have been reported to be clinical asymptomatic despite having PrP^{Sc} plaque deposition in the brain or shown to have late-onset neurologic symptoms with GSS-like pathology.

SPORADIC CREUTZFELDT-JAKOB DISEASE

Epidemiology

In most countries with adequate surveillance, the annual incidence of sCJD is estimated to range between 1 and 1.5 per 1 million population, with a slight growth over the past two decades likely contributed by the improvement of diagnostic methods and the rapidly growing aging population. The estimated median age of onset for sCJD is 60 to 67 years old, although with high variability, ranging between 12 and 95 years old. Young-onset sCJD (20s-40s) and onset after the age of 80 years are uncommon. Some studies suggest that sCJD cases with a younger age of onset tend to have longer survival and often present with noncognitive symptoms, including mood disorder, behavioral change, or sleep illnesses. The mean and median survival of sCJD is estimated to be 8 ± 11 months and 4.5 to 6 months (range, 1-130), respectively.

Clinical Presentation

Patients can present with a wide range of symptoms including cognitive impairment, behavioral changes, movement disorders, visual disturbances, and constitutional symptoms. Because of the varied presentations, sCJD often is called *the great mimicker*. A common early presentation is cognitive impairment, which may manifest as confusion, disorientation, memory decline, attention deficits, executive dysfunction, aphasia, and/or other higher cortical deficits. In a retrospective record review of 230 pathologically confirmed CJD cases, nearly all (96%) exhibited cognitive decline during their clinical course. Motor symptoms often include extrapyramidal symptoms (eg, bradykinesia, dystonia, tremor), cerebellar symptoms (eg, gait, or less commonly, limb ataxia), myoclonus, and/or pyramidal symptoms. Myoclonus can be spontaneous or startle provoked and may occur early in the classic sCJD variant (see next paragraph) or later in the disease course in some nonclassic forms. Extrapyramidal symptoms often include tremor (usually postural or with action), bradykinesia, cogwheeling, and/or movements. Pyramidal signs typically occur later in the disease course and typically include hyperreflexia or spasticity, but (in our experience) focal weakness is very rare. Typical behavioral symptoms seen in sCJD individuals include irritability, anxiety, depression, and, less commonly, psychosis. Other commonly reported clinical presentations or prodromes include constitutional symptoms (fatigue, malaise, headache, dry cough, light-headedness, vertigo, urinary incontinence, and sleep disturbance), visual symptoms (blurred or double vision and cortical blindness), and, less commonly, sensory symptoms (numbness, tingling, and/or pain).

Based on the initial presenting and predominant symptoms, sCJD has been classified into different clinical variants or presentations: classic (RPD, early and prominent myoclonus, often with a typical electroencephalogram [EEG] with periodic sharp wave complexes [PSWCs]), cognitive, Heidenhain (early and prominent visual symptoms), affective (early, prominent mood disorders), and Brownell-Oppenheimer (early, prominent ataxia) variants. In one of our own studies, with about 100 serial sCJD cases, the first clinical manifestations were cognitive in 40%, cerebellar, constitutional or behavioral in 20% for each, and extrapyramidal or pyramidal, visual or sensory symptoms in 10% or fewer of cases for each. In addition to having different initial presentations, these sCJD variants may differ in their clinical course, EEG, and brain magnetic resonance imaging (MRI) findings (see Diagnosis section). Classic and visual variants tend to be more rapidly progressive with a shorter disease course, whereas in one study the affective variant had the longest disease survival and younger age of onset compared to other variants. Conversely, the Oppenheimer-Brownell (ataxic) variant has an older age of onset and rarely exhibits PSWCs on EEG. Regardless of the sCJD variants, most sCJD cases will develop akinetic mutism (no purposeful movement and not speaking) at the end stage of the disease, with aspiration pneumonia being the most common direct cause of death.

Classic neuropathologic findings for sCJD include PrP^{Sc} deposition, vacuolation (formerly known as *spongiform changes*), neuronal loss without inflammation, and gliosis (proliferation of astrocytes) (Fig. 55.1). Pathologists have increasingly favored the term *vacuolation* over *spongiform changes* because the small cavities seen in the superficial cortical layers are fluid-filled vesicles formed in distal dendrites and not air-filled holes. Table 55.1 summarizes the clinical characteristics of several human prion diseases.

Molecular Classification

In addition to clinical phenotypes, sCJD has traditionally been subdivided into six "molecular" subtypes based on: (1) the genetic polymorphism at codon 129 in *PRNP* and (2) the prion type, the latter of which is determined by the molecular weight of PrP^{Sc} fragments after protease digestion. Type 1 prions are

FIGURE 55.1 **A** and **B** show stained histologic sections of frontal cortex and cerebellar cortex, respectively, stained with hematoxylin, eosin, and Luxol fast blue. **C** and **D** show immunohistochemically stained sections of frontal cortex and cerebellar cortex, respectively, stained with monoclonal antibody 3F4, specific for PrP^{res} (also called PrP^{Sc}). **A** and **C** are oriented with white matter up and pial surface downward. **A** shows prominent vacuolation of the gray matter more than the white matter, typical of prion-related spongiform change. **C** shows brown staining of granular deposits of abnormal prion protein, variably aggregated but more prominent in gray matter than white matter. **B** and **D** are oriented with cerebellar molecular layer up and granular cell layer downward. **B** shows minimal spongiform change but a prominent Kuru plaque *(arrow)*. **D** shows brown staining of granular deposits of abnormal prion protein in the molecular layer. (**A** and **B** courtesy of Dr. Jean Paul Vonsattel, Columbia University; **C** and **D** courtesy of Dr. Pierluigi Gambetti, Case Western Reserve University.)

21 kilodaltons (KDa) and type 2 are 19 KDa. By combining the codon 129 polymorphism and prion type, sCJD cases historically have been classified into six molecular subtypes: MM1, MV1, VV1, VV2, MV2, and MM2. As MM1 and MV1 share many similar clinicopathologically features, some large studies group them together as a single subtype, although they can have differences from each other, such as on MRI. The MM1/MV1 subtype is the most common accounting for about 70% of sCJD, with about 67.5 % being MM1 and 2.5% being MV1. The MM1/MV1 subtype typically presents as classic sCJD, with RPD, ataxia and myoclonus; a large minority of cases can have prominent visual or unilateral motor symptoms. It has the shortest disease duration with a median of about 4 months. The VV2 subtype is the second most common, comprising about 16% of sCJD cases. It generally manifests as the Brownell-Oppenheimer variant (ataxia) with late dementia and slightly longer medial duration of about 6 months and usually does not have a typical EEG. The MV2 subtype is third most common and represents about 9% of sCJD; similar to VV2 it usually presents with ataxia and does not have a typical EEG but has early progressive dementia and a longer median duration of 12 to 17 months. This subtype has been further divided and includes a large subset with focal amyloid "Kuru" plaques in the cerebellum and is referred to as the *Kuru plaque variant* or MV2K. The MM2 subtype is often subdivided into a cortical and a thalamic form, MM2-C and MM2-T, respectively, each representing approximately 2% of sCJD cases; both have median durations of about 12.5 to 15 months and usually do not have typical EEGs. MM2-C typically presents with progressive cognitive dysfunction and neuropathologically has confluent vacuoles in cortical layers, whereas MM2-T clinically often (but not always) resembles familial fatal insomnia with early insomnia and dysautonomia, followed by psychomotor hyperactivity, ataxia, and dementia at the later stage of the disease. This MM2-T form is also referred to as sporadic fatal insomnia

(sFI). Neuropathologically, MM2-T usually shows PrP^{Sc} deposition, but with very prominent gliosis and neuronal loss confined mainly to the thalamus and inferior olives, but little vacuolation (which probably explains why the MRI usually does not show restricted diffusion). VV1 is the rarest subtype (approximately 1%) with much younger, by about 15 to 20 years, median age of onset (39-47 y old) and a long disease duration of approximately 11 to 15 months, a large minority of sCJD cases have both type 1 and type 2 PrP^{Sc}. As the clinicopathologic phenotype appears to depend on the relative proportion of the two prion types, this supports the PrP^{Sc} type playing some role in determining the sCJD phenotype. Similarly, the codon 129 plays a large role in disease survival, with heterozygosity, MV, being associated with slower progression, independent of prion typing.

Diagnosis

Diagnostic criteria for sCJD have been modified several times due to improved diagnostic tests and increased understanding of the early presentations of the disease. Most sCJD criteria have three levels of diagnostic certainty: definite, probable, and possible (**Table 55.2**). Definite sCJD diagnosis requires evidence of PrP^{Sc} protein in infected tissue, either via immunohistochemistry or Western blot. Possible criteria generally are based on a constellation of symptoms alone, whereas probable criteria require symptoms plus a positive supportive diagnostic test (ie, EEG, MRI, and/or cerebrospinal fluid [CSF]). **Table 55.2** shows four commonly used diagnostic criteria for probable sCJD. Clinical features generally require a progressive dementia and include myoclonus, visual and/or cerebellar features, pyramidal or extrapyramidal features, and/or akinetic mutism. University of California, San Francisco (UCSF) criteria have added higher cortical dysfunction (ie, aphasia, apraxia, alien limb, neglect, etc) and separate out visual and cerebellar findings because in our experience, they do not necessarily co-occur and have very different anatomy. Biomarker tests for probable sCJD criteria include typical EEG (PSWCs), certain brain MRI findings (discussed in detail later), elevated CSF 14-3-3 protein (hereon referred to as "14-3-3") or a positive real-time quaking-induced conversion assay (RT-QuIC) from CSF or other tissue.

The most common EEG finding in sCJD is PSWCs, characterized by periodic sharp biphasic or triphasic waves, occurring about once every second (Fig. 55.2). Some large studies show only about 58% to 64% of sCJD cases have PSWCs during their disease course, and these findings usually present at late stage of the disease, with occurrence varying greatly based on the molecular classification (MM1: 73%, MV1: 53%, MV2/VV2/VV1: 12%-18%). Furthermore, PSWCs can be found in other neurologic illnesses, some which may share clinical features with sCJD, including Alzheimer disease, Lewy body disease, vascular dementia, hypoxic encephalopathies, progressive multifocal leukoencephalopathy, Hashimoto encephalopathy, and autoimmune-associated encephalopathy. Although this fact somewhat limits EEG's role in sCJD diagnosis by itself, by using criteria symptoms and other diagnostic tests (see the following paragraphs on CSF and MRI) may further increase diagnostic certainty for sCJD.

Numerous CSF proteins that reflect rapid brain cell injury have been proposed as sCJD diagnostic biomarkers, including 14-3-3, total tau, neuron-specific enolase (NSE), and the astrocytic protein S100β (S100β). The 14-3-3 was among the first proposed diagnostic biomarkers for sCJD and can be measured via Western blot or enzyme-linked immunosorbent assay. Due to the heterogeneity of the control groups and the different quantifying methods/protocols adopted, the sensitivity and specificity of these CSF biomarkers varies considerably among different publications and cohorts. Although, 14-3-3 is considered by many experts to be highly predictive of sCJD when there is a classic presentation LEVEL 1[1] but has limited value in atypical cases or less common subtypes its diagnostic utility remains an issue of controversy among CJD experts, however. In our own UCSF cohort of several hundred cases of RPD, 14-3-3 shows low sensitivity (approximately 55%) and specificity (approximately 70%-75%) for prion disease. Over time, the specificity of 14-3-3 has clearly been shown to be rather poor in large studies. One possible reason for the higher sensitivity for the 14-3-3 reported in studies from national prion surveillance centers, is that some centers have used it to screen for patients with CJD, thus sCJD patients with positive 14-3-3 are more likely to be referred to these national prion surveillance centers. For unclear reasons, European centers have often found higher diagnostic accuracy with 14-3-3 than North American centers. Nevertheless, an increasing number of studies have consistently shown several other CSF nonspecific biomarkers, such as total tau and NSE, to have better diagnostic sensitivity and/or specificity than 14-3-3. Among other non–prion-specific CSF biomarkers such as total tau, NSE, and S100β, several studies have indicated that CSF total tau as well as the ratio between phosphorylated tau to total tau have higher predictability in identifying sCJD. These CSF diagnostic markers, however, have much lower sensitivity and specificity for other forms of prion disease, such as vCJD and gPrDs. CSF neurofilament light chain (NfL) appears to have relatively high sensitivity for CJD but extremely low specificity because it is elevated in many neurodegenerative and related neurologic disorders. Several studies have also studied serum NfL and tau concentration as potential serum biomarkers and found them to be potential indicators for the severity and/or prognosis of prion diseases.

In contrast to previous biomarkers that reflect rapid neuronal injury, a relatively new test, RT-QuIC, detects PrP^{Sc} itself. This method allows detection of very small quantities of PrP^{Sc} that might be present in a sample (eg, CSF) by amplifying it. The sample to be tested to determine if it contains PrP^{Sc} is pipetted onto a microwell plate containing PrP^{C} substrate. When the plate is shaken, if any PrP^{Sc} is present in a well, this promotes conversion of the PrP^{C} substrate into PrP^{Sc}. PrP^{Sc} eventually forms amyloid fibrils, which bind thioflavin T that is added to the mixture, thereby emitting a fluorescent signal to reflect the presence of PrP^{Sc}. Multiple tissues have been investigated using RT-QuIC, including brain tissue, CSF, nasal mucosa, skin, and eye tissues (retina, optic nerve, extraocular muscle, choroid, lens, vitreous, and sclera). Depending on the study, the substrate used and assay conditions, RT-QuIC sensitivity and specificity generally ranges between 77% to 97% and 98% to 100%, respectively. Thus, RT-QuIC is regarded as useful minimally to mildly invasive ante mortem test to confirm a sCJD diagnosis in the proper clinical context LEVEL 1,[2] but certainly negative results do not exclude the disease.

Brain MRI as a diagnostic tool for sCJD has evolved considerably over the past three decades. The first identified MRI characteristics were increased signal intensity in basal ganglia on T2-weighted scans. Later, cortical gyral hyperintensities, commonly referred to as *cortical ribboning*, on fluid-attenuated inversion recovery (FLAIR) and DWI MRI sequences were noted to be more sensitive indicators for sCJD. These MRI abnormalities,

TABLE 55.2 Diagnostic Criteria for Sporadic, Genetic, Variant, and Iatrogenic Creutzfeldt-Jakob Disease[a]

	Sporadic CJD	Genetic CJD	Variant CJD	Iatrogenic CJD
Definite	Progressive neurologic syndrome **AND** Neuropathologically **OR** Immunocytochemically **OR** Biochemically confirmed	• Definite TSE **AND** • Definite or probable TSE in first-degree relative **OR** • Pathogenic *PRNP* mutation[b]	Progressive neuropsychiatric disorder **AND** Neuropathologic confirmed[c]	Definite CJD with a recognized iatrogenic risk factor[d]
Probable	Rapidly progressive cognitive impairment with two of the following: • Myoclonus • Visual or cerebellar disturbance • Pyramidal or extrapyramidal signs • Akinetic mutism **AND** • Typical EEG[e] **OR** • Typical MRI[f] **OR** • Elevated CSF 14-3-3 **OR** Progressive neurologic syndrome with a positive RT-QuIC in CSF or other tissues	Progressive neuropsychiatric disorder **AND** • Definite or probable TSE in first-degree relative **OR** • Pathogenic *PRNP* mutation[b]	• Progressive neuropsychiatric disorder • Duration of illness >6 mo • Routine investigations do not suggest an alternative diagnosis • No history of potential iatrogenic exposure • No evidence of a familial form of TSE **AND** Four of the following: • Early psychiatric features[g] • Persistent painful sensory symptoms[h] • Ataxia • Myoclonus or chorea or dystonia • Dementia **AND** Positive tonsil biopsy **OR** EEG does not show the typical appearance of sporadic CJD in the early stages of illness.[e] **AND** Bilateral pulvinar high signal on MRI scan	• Progressive predominant cerebellar syndrome in human pituitary hormone recipients **OR** • Probable CJD with a recognized iatrogenic risk factor[d]
Possible	Rapidly progressive cognitive impairment with two of the following: • Myoclonus • Visual or cerebellar disturbance • Pyramidal or extrapyramidal signs • Akinetic mutism **AND** Disease duration <2 y		• Progressive neuropsychiatric disorder • Duration of illness >6 mo • Routine investigations do not suggest an alternative diagnosis. • No history of potential iatrogenic exposure • No evidence of a familial form of TSE **AND** Four of the following: • Early psychiatric features[g] • Persistent painful sensory symptoms[h] • Ataxia • Myoclonus or chorea or dystonia • Dementia **AND** EEG does not show the typical appearance of sporadic CJD in the early stages of illness.[e]	• Possible CJD with a recognized risk factor[d]

Abbreviations: CJD, Creutzfeldt-Jakob disease; CSF, cerebrospinal fluid; EEG, electroencephalogram; MRI, magnetic resonance imaging; RT-QuIC, real-time quaking-induced conversion assay; TSE, transmissible spongiform encephalopathy.

[a]Criteria are borrowed (with slight modifications) with permission from UK National Creutzfeldt-Jakob Disease Research & Surveillance Unit. Diagnostic criteria for human prion disease. National CJD Research & Surveillance Unit Web site. https://www.cjd.ed.ac.uk/diagnostic-criteria. Updated January 2017. Accessed August 28, 2019.

[b]Pathogenic *PRNP* mutations include P102L, P105L, A117V, G131V, F198S, D202N, Q212P, Q217R, M232T, 192 bpi, D178N-129V, V180I, V180I + M232R, T183A, T188A, E196K, E200K, V203I, R208H, V210I, E211Q, M232R, 96 bpi, 120 bpi, 144 bpi, 168 bpi, 48 bpdel, D178N-129M, Y145s, H187R, 216 bpi, I138M, G142S, Q160S, T188K, M232R, 24 bpi, 48 bpi, and 48 bpi + nucleotide substitution in other octapeptides.

[c]Spongiform change and extensive prion protein deposition with florid plaques throughout the cerebrum and cerebellum.

[d]Treatment with human pituitary growth hormone, human pituitary gonadotrophin or human dura mater graft, corneal graft in which the corneal donor has been classified as definite or probable human prion disease, or exposure to neurosurgical instruments previously used in a case of definite or probable human prion disease.

[e]Typical EEG: periodic sharp waves complexes.

[f]Typical MRI for European Consortium 2017 criteria: High signal abnormalities in caudate nuclei and putamen or at least two cortical regions (temporal-parietal-occipital but not frontal, cingulate, insular, or hippocampal) either on diffusion-weighted imaging or fluid-attenuated inversion recovery MRI. Note: The authors of this chapter consider the University of California, San Francisco (UCSF) sporadic CJD MRI criteria (Staffaroni et al., 2017) to be far more sensitive and specific than the European Consortium MRI criteria (Zerr et al., 2009).

[g]Depression, anxiety, apathy, withdrawal, delusions.

[h]Includes frank pain and/or dysesthesias.

[i]Tonsil biopsy is not recommended routinely nor in cases with EEG appearances typical of sporadic CJD but may be useful in suspect cases in which the clinical features are compatible with variant CJD and MRI does not show bilateral pulvinar high signal.

FIGURE 55.2 Electroencephalogram tracings show pseudoperiodic generalized paroxysmal discharges. The electroencephalogram montage shows generalized paroxysmal discharges with a sharp, often triphasic, morphology that occur in a nearly periodic fashion of about one per second. Amplitude is somewhat greater in the frontal regions.

however, are much more evident on DWI than on T2 or even FLAIR sequences (Fig. 55.3). Such DWI hyperintensities in sCJD are due to restricted diffusion (of water molecule flow likely due to vacuolation), and thus there is usually corresponding decreased signal intensity on apparent diffusion coefficient (ADC) map sequences. It is important to confirm on MRI that this DWI hyperintensity has corresponding ADC hypointensity because some brain regions, particularly areas with air-brain interface, are artefactually hyperintense on DWI or T2 and not true restricted diffusion. The pattern and sensitivity of MRI findings varies considerably among the six sCJD molecular subtypes (Fig. 55.4). For instance, VV1 often does not have basal ganglia hyperintensity on T2 or DWI, whereas more than 50% of VV1, MM2, and MV1 subtypes have cortical ribboning, and thalamic hyperintensity is found more commonly (approximately 45%) in VV2 and MV2 but in less than 10% of MM1 and VV1 and in about 20% to 35% of MV1 and MM2 subtypes. The diagnostic accuracy of MRI in sCJD may be affected by the MRI acquisition sequences used and the radiologists' experience. Obtaining higher b values, such as b2000, rather than the typical b1000, on DWI and ADC map reduces air-brain artifacts and allows improved detection of cortical ribboning from background. As knowledge of MRI features of sCJD has improved, MRI criteria have also been modified to improve diagnostic accuracy. The UCSF 2017 sCJD MRI criteria (see Staffaroni et al., 2017) emphasize the importance of diffusion over T2 and FLAIR sequences because abnormal signal usually is more evident on diffusion sequences. Furthermore, with optimal acquisition protocols (eg, b2000 DWI, ADC and exponential ADC images acquired in multiple directions), brain regions previously considered to have a lot of artefact—such as frontal and insular cortices, cingulate gyrus, and anterior temporal lobes—now can be incorporated as regions of interest in sCJD MRI criteria (see **Table 55.2**). In general, the sensitivity and specificity of brain MRI for sCJD range from 91% to 96% LEVEL 2.[3]

GENETIC PRION DISEASE

Unlike most "infectious" disease, 10% to 15% of prion diseases are of genetic etiology and caused by mutations in *PRNP* (see **Table 55.2**). To date, there are more than 60 *PRNP* variants reported, with the majority being missense mutations; all are autosomal dominant inheritance pattern and most are highly penetrant. Some variants initially purported to be pathogenic, however, are frequent enough in the normal population that they are likely either risk factors, very low penetrance pathogenic variants (ie, mutations) or even nonpathogenic. Worldwide, about 85% of gPrDs are caused by five missense *PRNP* mutations: E200K, V210I, V180I, P102L, and D178N. In one large European study, nearly half of the gPrD cases (47%) identified had a negative family history, although with wide variations among the major mutations (E200K, 49.1%; V201I, 12.3%; FFI, 88%). Two primary reasons for these negative family histories are likely misdiagnoses of previous cases in the family (such as Alzheimer or Parkinson disease) or that the disease was hidden from family members or branches of a family, both of which

FIGURE 55.3 The image depicts the brain magnetic resonance imaging of a sporadic Creutzfeldt-Jakob disease patient in three different imaging sequences: fluid-attenuated inversion recovery (FLAIR), diffusion-weighted imaging (DWI), and apparent diffusion coefficient (ADC). Diffuse cortical gyral hyperintensities *(angled arrows)* (*"cortical ribboning"*) are shown on FLAIR and DWI sequences, most prominent over the bilateral frontoparietal lobes and caudate nuclei (*arrows* at bilateral parietal and caudate nuclei). Corresponding hypointensity is present on ADC sequences *(arrows)*. These findings show that these imaging abnormalites are due to restricted diffusion of water molecules and are the typical imaging findings in the vast majority of sporadic Creutzfeldt-Jakob disease cases.

are quite common. With some mutations, such as V210I, V180I and others, family histories might have been missed because the *PRNP* mutation was not fully penetrant. In rare cases, the mutation may have been de novo. It is for this reason that we prefer not to use the term *inherited prion disease* but rather gPrD.

The original classification of familial prion diseases into fCJD, GSS, and FFI was based on clinicopathologic features and before the discovery of *PRNP*. This historical classification system is inadequate based on our current understanding of the genetic origin of familial prion disease and the variety of *PRNP* mutations that can cause prion disease. For example, several *PRNP* mutations, such as OPRIs and stop codons do not fit neatly into any of the three historical classification groups. Similar to many genetic forms of other neurodegenerative diseases, the genotype and phenotype are not fully correlated in gPrDs; thus, the clinical presentations can vary considerably within the same pathogenic variant or even within the same family, which makes classification based on clinical-pathogenic features problematic. Because of the common use of the historical clinicopathologic classification of gPrDs—fCJD, GSS and FFI—we use these terms in our discussion of gPrDs but also discuss mutations based on other features, such as the variant location, and discuss OPRI and stop codon mutations separately (see Table 55.1). We briefly review gPrDs in the following sections, but more comprehensive reviews are listed in the "Suggested Readings" section.

Familial Creutzfeldt-Jakob Disease

For most *PRNP* mutations that are classified as fCJD, patients generally present similarly to sCJD clinically and pathologically, other than having a younger age of onset (approximately 7 y younger). There are more than 20 *PRNP* missense variants reported including but not limited to P105T, G114V, R148H, D178N (codon 129 cis V), V180I, T183A, T188A, T188K, T188R, T193I, K194E, E196A, E196K, E200K, E200G, V203I, R208H, V210I, E211Q, I215V, A224V, M232R, and P238S, although a few of these are of unclear pathogenic significance (eg, M232R) or have very low penetrance (eg, V180I, V210I). *PRNP* missense mutations, OPRIs with four (or possibly fewer) 24-base pair (octapeptide) repeats and a two octapeptide deletion usually manifest as fCJD. OPRIs are discussed in more detail in the following text. The E200K mutation is the most common *PRNP* pathogenic variant worldwide. Although resembling sCJD clinically, some individuals with E200K mutation have been reported to develop symptoms atypical for sCJD. Such symptoms include pruritus, demyelinating

FIGURE 55.4 Each row shows an axial diffusion-weighted imaging MRI (DWI) sequence of a different patient with definite sporadic Creutzfeldt-Jakob disease (sCJD). These rows show the variable involvement of cortex and deep nuclei (striatum and/or thalami) in sCJD. For the patient whose MRI is shown on the **top row**, prominent cortical ribbon hyperintensity can be seen in the parieto-occipital cortex bilaterally, but there is no clear signal abnormality in the deep nuclei. In the patient's MRI shown in the **middle row**, there is prominent abnormal hyperintensity in the striatum and thalami bilaterally but much less cortical ribboning (bilateral anterior cingulate and left inferior lateral temporal). In the **bottom row**, the patient's images show hyperintense abnormalities in the striatum and cortex, as well as the insula and hippocampal tails or posterior parahippocampal gyri.

peripheral neuropathy, and supranuclear gaze palsy, and there may be a higher prevalence of headache and seizure when compared to sCJD. There is also some data suggesting certain E200K cases, particularly those from Western and Eastern Europe, can be distinguished from sCJD by the presence of pathologic inclusions. Patients with the D178N mutation with valine at the cis codon 129 generally present as sCJD phenotype, whereas those with cis methionine at codon 129 typically manifest as FFI, showing a strong effect of the codon 129 polymorphism on the clinicopathologic presentation. The relationship of D178N and the codon 129 polymorphism, however, is by no means invariable—some cases with cis 129 valine present as FFI, and some with cis 129 methionine present as CJD. FFI is discussed in more detail in the following text. In contrast to E200K, D178N, and many other pathogenic variants that have high penetrance approaching 100%, the V210I, V180I, and M232R *PRNP* variants have much lower penetrance, estimated to be around 10%, 1%, and 0.1%, respectively. Most V180I cases tend to progress slower with a mean disease duration of about 25 months. Among M232R cases of prion disease, about three-quarters of cases have a relatively rapidly progressive course (disease duration, 12.5 ± 10.9 mo) and have type 1 PrP^{Sc} with synaptic-type depositions. The remaining 25% of cases have a much slower disease course (disease duration, 49.9 ± 53.8 mo) and more often have type 2 PrP^{Sc} with perivacuolar depositions and spongiform changes. Most M232R and V180I cases have been identified in Japan.

Gerstmann-Sträussler-Scheinker Disease

The eponymous name GSS was first introduced in 1980 in honor of some of the authors that first reported the disease in an Austrian family. GSS typically presents with slow progressive cerebellar ataxia with gait disturbance (72%), accompanied by cognitive impairments (82%), psychiatric symptoms (21%), speech and swallowing problems, parkinsonism (36%), and myoclonus (15%) at the later stage of the disease. The age of symptom onset is usually in one's 50s, but can range widely, between the second and the seventh decades. Although disease duration in GSS is quite variable, in general, survival ranges from a few years to a decade or more, much longer than most other prion diseases. Some GSS cases, however, can present with RPD with survival of 1 year or less. The majority of the GSS cases have a positive family history (69%-100%) with autosomal dominant inheritance and penetrance estimated to approach 100%. More than 19 *PRNP* missense mutations (including but not limited to P84S, P102L, P105L, P105S, P105T, A117V, G131V, S132I,

A133V, R136S, V176G, H187R, F198S, D202N, E211D, Q212P, Q217R, Y218N, and M232T), several stop codon mutations (Y145X, Q160X, Y163X, Y226X, and Q227X), and OPRI variants have been linked to a GSS phenotype, with P102L being the most common *PRNP* mutation causing GSS worldwide, and also the first *PRNP* mutation identified. Neuropathologic features of GSS includes PrP^{Sc}-amyloid plaques (ie, prion proteins aggregate and form large uni- or multicentric amyloid plaques that deposit the cerebellum and cerebral cortices), PrP^{Sc}-related amyloid angiopathy (ie, PrP^{Sc}-immunoreactive amyloid depositions within the cerebral vessels wall), and vacuolation (ie, spongiform changes). Given the neuropathologic findings of PrP^{Sc}-amyloid plaques and the dominant inheritance pattern, GSS is sometimes referred as *dominantly inherited PrP cerebral amyloidosis*. Most biomarkers used for diagnosis of sCJD are less sensitive in GSS. The EuroCJD study conducted by the European Creutzfeldt-Jakob Disease Surveillance Network reported that only 50% patients with GSS had elevated CSF 14-3-3, fewer than 10% had PSWCs on EEG and only about 30% showed MRI findings typically found in sCJD (**Fig. 55.5**). Because of its somewhat slowly progressive clinical presentation and often negative ancillary tests for prion disease, GSS is often mistaken for other neurodegenerative conditions, such as multiple system atrophy, spinocerebellar ataxias, idiopathic Parkinson disease, Alzheimer disease, or Huntington disease, unless *PRNP* analysis is performed. GSS can even be missed pathologically, as the PrP^{Sc}-amyloid plaques are sometimes mistaken for amyloid-β if specific immunohistochemistry for abeta-amyloid and PrP are not used. In view of the PrP^{Sc}-amyloid plaque deposition in GSS, researchers are investigating the feasibility of using amyloid-binding positron emission tomography (PET) tracers such as 2-(1-(6-[(2-[^{18}F] fluoroethyl) (methyl) amino]-2-naphthyl)ethylidene) malononitrile ([^{18}F]FDDNP) to diagnose GSS.

Fatal Familial Insomnia

FFI classically presents with somewhat insidious onset over months of progressive insomnia and dysautonomia with the latter including symptoms such as tachycardia, hyperpyrexia, fluctuating blood pressure, episodic hyperventilation, hyperhidrosis, sexual dysfunction, and/or urinary incontinence. This is usually followed by truncal and appendicular ataxia, brainstem signs (gaze and swallowing abnormalities), with profound confusion and cognitive problems appearing later in the course. For those with insomnia, vivid dreams can be common during limited sleep. Cognitive symptoms often manifest as slow processing speed, decreased attention, and impairment in short-term memory that eventually progresses to a state of delirium. As noted in earlier discussion, persons with FFI usually have *PRNP* D187N missense variant with cis-methionine codon 129

FIGURE 55.5 The image shown here is the T1 sequence brain magnetic resonance imaging of a 46-year-old patient who presented with a Gerstmann-Sträussler-Scheinker clinical phenotype, and further genetic testing revealed a six octapeptide repeat insertion *PRNP* mutation. Note that the MRI reveals diffuse brain atrophy, most evident over the bilateral parietal *(arrows)* and frontal lobes, as well as to a lesser extent the superior cerebellum. No abnormal cortical or subcortical hyperintensity was found on fluid-attenuated inversion recovery and diffusion-weighted imaging sequences, nor was there any restricted diffusion commonly foiund in sCJD.

(D178N-129M), but some D178N-129M cases present as sCJD, and some D178N-129V cases present as FFI. Even within the same family, different presentations can occur. FFI (D178N-129M) has been reported in about 30 families worldwide, with a mean age at symptom onset of about 52 years (range, approximately 20-76 y), and an average disease duration of 13.5 months (range, 4-40 mo). Some studies note that individuals with D178N-129M, who are heterozygous (MV) at codon 129 (ie, trans V), have longer disease durations (mean, approximately 23 mo) compared to individuals who are codon 129 MM (mean, approximately 11 mo), suggesting an effect of the trans codon 129 polymorphism in this disease as well. Whereas brain MRI is often unremarkable, fluorodeoxyglucose (FDG)-PET imaging frequently displays marked thalamic, and sometimes cingulate, hypometabolism, which may be present even prior to disease onset. Neuropathologically, individuals with FFI typically exhibit marked neuronal loss and atrophy in the anterior ventral and dorsomedial thalamic nuclei and the inferior olivary nucleus. Frequently, there is also cerebellar Purkinje cell loss which is frequently associated with fusiform axonal swelling in the granule cell layer called axonol "torpedoes."

Octapeptide Repeat Insertions

The N-terminal of the normal prion protein consists of a nonapeptide (Pro-Gln-Gly-Gly-Gly-Gly-Trp-Gly-Gln), named R1, followed by four octapeptide (24-base pair) repeats, named R2-R2-R3-R4, each with the same amino acid sequence (Pro-His-Gly-Gly-Gly-Trp-Gly-Gln) but R3 and R4 differ slightly from each other and R2 at two nucleotides. Thus, a normal variant of the tandem repeats is termed *R1-R2-R2-R3-R4* and is referred to as the *octapeptide repeat region of PRNP*, which is a copper-binding region of the protein. Perhaps due to unequal crossover during recombination process or faulty replication process, deletion of two octapeptide repeats or insertion of four or more octapeptide repeats in *PRNP* gene have been associated with gPrDs. The 1-OPRI variant is considered to be nonpathogenic. Although two and three OPRIs have been reported as pathogenic in a few reports, their pathogenicity is an issue of debate, and many consider them to be nonpathogenic variants based on their frequencies in the general population and/or that when identified in more than one family member with dementia, only one family member clearly had prion disease (clinically or pathologically) and the prion disease resembled sCJD. OPRIs have been shown to produce protease-resistant aggregation-prone PrP^{C} protein, thus predisposing the formation of PrP^{Sc}. The clinical and pathologic phenotype of OPRIs has been reported to be somewhat correlated with the number of octapeptide repeats. Most individuals with four OPRIs manifests as sCJD with shorter disease course, and there is a question as to whether 4-OPRI is a low penetrance pathogenic variant or requires another polymorphism for it to be deleterious. OPRIs of five or more have more clearly been shown to be pathogenic, however. Individuals with five to seven OPRIs have heterogenous clinical phenotypes and often have long clinical courses of several years, with age of onset varying from 20s to 80s, although most commonly 20s to 40s, and pathology usually shows elongated PrP^{Sc} deposits. Patients with eight or more OPRIs tend to have clinical and pathological overlap with GSS, although there is great clinicopathologic variability. One 8-OPRI family was reported to have a Huntington disease–like presentation and considered to be a Huntington disease phenocopy. The only 12-OPRI family reported has a frontotemporal dementia–like presentation and is also a tauopathy on pathology and on tau-PET imaging.

In our experience, many commercial laboratory standard dementia gene panels, particularly those using next-generation sequencing, can miss expansions or deletions in *PRNP*. Thus, if a result is negative, but gPrD is still suspected, we would recommend that a blood sample be sent to a laboratory that does Sanger sequencing of *PRNP* or uses other methods that are sensitive for detection of deletions and expansions.

ACQUIRED PRION DISEASE

Acquired prion diseases are "transmitted" forms of prion diseases and include three different prion disease types: Kuru, iCJD, and vCJD. Kuru was the first known acquired prion diseases, identified in the Fore people of Papua New Guinea (see Table 55.1). It was transmitted among the Fore people thru the endocannibalism of deceased relatives as a mourning ritual. As woman and children more often consumed the brain and viscera, including nervous system tissue, they were more at risk for consuming prions and contracting the disease than the adult men. The term *Kuru* means "to shake or tremble" in Fore language, as the disease typically presents as slow progressive cerebellar ataxia, sometimes accompanied by tremor, chorea and athetoid movements. The incidence of Kuru greatly diminished when missionaries stopped the endocannibalism rituals in the 1950s. Kuru is essentially extinct, except very rare new cases in persons born before the cessation of endocannibalism, showing the incubation period can be as long as 50 years, especially in individuals whom are heterozygous, MV, at *PRNP* codon 129. Interestingly, a very clever study examining the genetics of females who lived in the region of Kuru and survived the epidemic identified a *PRNP* polymorphism at codon 127 that appears to be protective against prion disease. Furthermore, mice with this polymorphism appear to be resistant to prion disease. Understanding of the mechanism of this polymorphism might help lead to therapies for prion diseases. As Kuru is essentially extinct, the remainder of this section mainly focuses on vCJD and iCJD.

Variant Creutzfeldt-Jakob Disease

vCJD was first described in 1995 and soon after raised much public concern when it was linked to the bovine spongiform encephalopathy (BSE) epidemic. Compelling evidence support that the majority of vCJD cases were exposed to the disease through the inadvertent consumption of meat and offal contaminated with BSE, commonly known as *mad cow disease*. It is believed that BSE emerged because of the practice of feeding cattle the body parts of sheep that were contaminated by scrapie. As of January 2020, about 229 vCJD cases have been officially reported worldwide, with 178 of the cases diagnosed in United Kingdom, 28 in France, 5 in Spain, 4 each in United States and Ireland, 3 each in Italy and Netherlands, 2 each in Portugal and Canada, and 1 each in Taiwan, Japan, and Saudi Arabia. Several cases, particularly those outside of the United Kingdom and France, were likely exposed in a different country than where they were diagnosed. Through the strong implementation of import control and feeding regulations, the incidence of vCJD has drastically decreased since the year 2000 and to our knowledge, no new cases has been officially reported from 2017 through at least the end of 2019.

vCJD typically manifests initially with psychiatric symptoms such as depression, anxiety, irritability, and apathy. This usually is followed by persistent painful paresthesias, cognitive impairment, cerebellar ataxia, and/or motor symptoms such as

FIGURE 55.6 Brain magnetic resonance imaging of a patient with variant Creutzfeldt-Jakob disease case. **A:** Note that on the T2-weighted imaging, there are hyperintensities in the bilateral pulvinar nuclei *(black arrows)* and to a lesser degree in the bilateral caudate and putamen. The pulvinar being more hyperintense than the anterior putaman is referred to as the *pulvinar sign*. **B:** Corresponding pulvinar hyperintensities are also noted on the proton-density weighted images. **C:** Signal intensity quantification of the pulvinar relative to the anterior putamen on fluid-attenuated inversion recovery images. The pulvinar signal intensity is 25% higher when compared with the putamen area, which is consistent with the pulvinar sign. (Images borrowed with permission from Collie DA, Sellar RJ, Zeidler M, Colchester CF, Knight R, Will RG. MRI of Creuztfeldt-Jakob disease: imaging features and recommended MRI protocol. *Clin Radiol*. 2001;56[9]:726-739.)

myoclonus, chorea, or dystonia. In contrast to most prion diseases, vCJD generally affects younger pateints, with median age of symptom onset around 26.5 years (range, 12-74 y). vCJD is considered to have longer disease duration compared to sCJD, averaging around 14.5 months. Unlike sCJD in which PSWCs on EEG are eventually found in about two-thirds of cases, EEG in vCJD rarely shows these specific abnormalities and even then, only at the end stage of the disease. Brain MRI in vCJD usually shows involvement of the thalamus. This, however, is not unique to vCJD; the pulvinar sign in which pulvinar hyperintensity is brighter than the anterior putamen or other basal ganglia, particularly on T2-weighted proton-density sequences (probably also on DWI as well) has at least 79%, and probably much higher, sensitivity for vCJD and relatively high specificity for vCJD versus other prion diseases (Fig. 55.6). T2-weighted hyperintensities of the medial dorsal thalamus and pulvinar, making the so-called hockey stick sign, or double hockey-stick if bilateral, can be seen in vCJD as well, but is less specific than the pulvinar sign, and such thalamic hyperintensities can be found in other prion and nonprion disorders. As with other prion diseases, in long-lived cases, these MRI hyperintensities on T2-weighted or DWI MRIs may eventually disappear, usually where there is significant atrophy.

In vCJD, PrP^{Sc} can be detected not only in the nervous system but also in the lymphoreticular system, including lymph nodes, tonsils, spleen, and appendix. PrP^{Sc} fibrillary protein aggregates around groups of vacuoles and form flower-like (florid) plaque appearance, the pathognomonic neuropathologic hallmark of vCJD. PrP^{Sc} from vCJD also has a distinct profile on Western blot, differentiating it from most other prion diseases. Given the peripheral distribution of PrP^{Sc} in vCJD cases, sampling the tonsillar tissue to detect the presence of PrP^{Sc} has been included as one of the diagnostic criteria for probable vCJD. Some research studies have shown that PrP^{Sc} can be detected in the urine and in blood in vCJD, but these tests are not available clinically. Similar to sCJD, the diagnosis of vCJD is divided into definite, probable, and possible categories based on the level of diagnostic certainty (see **Table 55.2**). Unlike other prion diseases, vCJD has been proven to be transmissible by blood, even from blood of preasymptomatic patients (who carry vCJD prions in their blood). Interestingly, the three receipients of vCJD-contaminated blood who ultimately developed clinical vCJD were MM-homozygotes at codon 129 in *PRNP*, whereas the two recipients who died of other causes but at autopsy were found to have vCJD prions outside their nervous system were heterozygous for MV. Furthermore, to date, all reported vCJD cases have been homozygous for MM at codon 129, with the rare exception of one (or possibly two) being MV, suggesting that individuals with the codon 129 MM polymorphism may be more susceptible to vCJD. Two large-scale studies in the United Kingdom found that 1 in 2,000 to 1 in 4,000 of stored appendix tissue samples were positive for PrP^{Sc}, raising safety concerns of the blood products provided by the residents for vCJD-affected countries.

Iatrogenic Creutzfeldt-Jakob Disease

iCJD occurred because cases of prion disease were undiagnosed prior to undergoing certain medical procedures, and routine sterilization methods in medical practice had not been (and some still currently are not) targeted toward inactivating prions. This has led to human-to-human transmission of prions through a few medical procedures. iCJD was first reported in 1974, and as of

around 2016, 492 cases worldwide have been reported. This includes cases that received cadaveric human pituitary hormones (growth hormone and gonadotrophic hormone), dura mater graft transplants, corneal transplants, or whom were operated on inadvertently with prion-contaminated neurosurgical instruments or EEG stereotactic depth electrodes (see Table 55.2).

Approximately 238 cases of human growth hormone associated iCJD had been reported worldwide as of 2016. Individuals with growth hormone associated iCJD tend to have long incubation periods (mean, 17 y, ranging from 5 to 24 y). Most cases have *PRNP* codon 129 MM genotype. Typically, patients with iCJD present with cerebellar motor symptoms and with cognitive impairment occurring at the late stage of the disease. In United States, there have been no reports of iCJD cases whom received growth hormone after the year 1977, which is the year when a highly selective column chromatography step was introduced into the purification protocol for human growth factors. It is possible and even likely that there will be future cases presenting after long incubation periods from remote exposures.

The first case of dura mater graft associated iCJD was reported in 1987, and there were roughly 238 cases officially reported worldwide as of 2016, with 60% of the reported cases occurring in Japan. Most contaminated dura mater graft were batches of a product called *Lyodura*, manufactured by a German company B. Braun Melsungen AG, which combines dura mater from many human cadavers; unfortunately, some of the donors at the time of dura mater removal were not realized to have prion disease. Lyodura was used worldwide, although most widely in Japan where it was used for a wide variety of medical procedures. The mean incubation period for dura mater graft–associated iCJD is about 12 years (ranging from 1.3 to 30 y). Two-thirds of the dura mater graft–associated iCJD cases present as sCJD clinically, with rapid progression of cognitive, cerebellar, and visual symptoms, often with PSWCs on EEG and no PrP^{Sc} plaques in the brain. The remaining one-third of cases are more slowly progressive, have PrP^{Sc} plaques in the brain and rarely show PSWCs on EEG. Some evidence suggests that the slower dura mater iCJD subgroup were infected by dura matter from VV2 or MV2 sCJD patients and the more common subgroup from MM1/MV1 sCJD dura mater.

There are at least four reports of possible neurosurgical instruments transmitted iCJD cases: three in the United Kingdom and one in France. The time interval between cranial surgery to symptoms onset range between 1.4 and 2.2 years. The identification of these cases is challenging given that they clinically resemble sCJD, and the source cases were not easy to trace. Other reported transmission routes include corneal transplant, EEG depth electrodes, and blood transfusion (from persons who later developed vCJD with some recipients later developing vCJD). The World Health Organization has guidelines on best practices for decontaminating prions from medical and surgical equipment.

MANAGEMENT AND OUTCOMES

Symptomatic Treatments

To date, there are no curative or disease modifying treatments available for any form of prion disease. There are various nonpharmacologic management strategies and pharmacologic treatments to alleviate some of the symptoms commonly seen in persons suffering from prion disease. In general, nonpharmacologic management is recommended prior to starting pharmacologic treatments, unless intervention is urgently required. Given that human prion evolve quickly over their course, medication lists should be assessed periodically to optimize management of symptoms and to avoid overmedication. Table 55.3 lists some supportive and symptomatic treatments for various common symptoms in prion disease.

Any medicines mentioned in this chapter need to be used cautiously to avoid or reduce side effects. Nutrition and feeding are important aspects to manage in prion disease because almost all patients with prion disease will ultimately die from aspiration pneumonia. Swallowing assessments are recommended at baseline and/or when patients exhibit speech difficulties, choking signs, or decreased food/fluid intake. If feeding is complicated by motor difficulty, depending on the symptoms ergonomic utensils may facilitate self-feeding. To encourage adequate food intake, frequent reminders on meal schedule and being flexible on diet preferences can be considered. Oral hygiene care such as using a child's toothbrush, washcloth, or swab may lower the risk of aspiration pneumonia and maintain comfort care. When dysphagia is present, adding thickener to liquids, chopping up food into small pieces, and giving small amounts at a time can decrease choking episodes. We generally recommend against feeding tubes, which can extend survival in prion disease but usually do not improve quality of life and may worsen it by extending suffering of patients and families. As prion diseases often impact cognitive function early in the disease course, advance care planning while patients are still cognitively competent is important.

Investigational Treatments

There are no effective treatments or cures to stop or reverse the disease course for human prion disease. Several medications have been tried, but none has been successful. Of the four medications have formally tested in human prion disease, only three were tested in appropriate randomized, controlled trials (oral flupirtine, oral quinacrine, oral doxycycline, and intrathecal pentosan polysulfate [PPS]), and none showed improved survival. Flupirtine was tested in a small randomized, controlled trial of 28 patients with CJD in Germany and showed some mild brief improvement in cognition but showed no benefit in survival. The antimalarial quinacrine inhibited conversion of PrP^{C} into PrP^{Sc} in vitro, but observational studies in the United Kingdom and France and a randomized, double-blinded, placebo-controlled trial in the United States showed no improved survival. Doxycycline showed potential effect in vitro and in small animal models but revealed no benefit in survival or other outcomes in a randomized, controlled trial of symptomatic prion disease. Nevertheless, it is being studied in an ongoing clinical trial in presymptomatic FFI mutation carriers in a large Italian family to see if it can delay the average age of onset compared to historical controls. PPS showed promise in some animal models, even when given after symptom onset, but needs to be administered intraventricularly because it does not cross the blood-brain barrier. It is controversial as to whether PPS had any benefit in human case reports or observational studies. It might have shown some reduction of PrP^{Sc} or other expected pathology. In vCJD, it may have prolonged duration of disease in some cases but did not result in symptomatic improvement. As of 2020, there is an experimental treatment being given to qualified patients with symptomatic prion disease using an experimental monoclonal antibody, PRN100, against the prion protein through the United Kingdom National Health Service at the Medical Research Council in London, United Kingdom for (eg, sCJD) that is

TABLE 55.3 Nonpharmacologic and Pharmacologic Managements of Human Prion Disease

	Nonpharmacologic	Pharmacologic (Off-label)
Myoclonus	• Minimizing environmental auditory and tactile stimuli • Limiting number of visitors • Keep bed in a quiet area.	• Benzodiazepine (eg, clonazepam) • Antiepileptic medications (eg, levetiracetam, valproic acid)
Pain/dysesthesia	• Identify and manage source of pain.	• Nonneuropathic pain: acetaminophen, opioids, other • Neuropathic pain: antiepileptic (eg, pregabalin, gabapentin, eslicarbazepine, carbamazepine) and serotonin-noradrenaline reuptake inhibitors (SNRIs; eg, duloxetine). Beware of central nervous system depression.
Psychosis/agitation/irritability	• Risk assessment and care resource evaluation • Identifying and removing precipitating factors • Art, soft music, and aroma therapy	• Selective serotonin reuptake inhibitors (SSRIs; eg, escitalopram and citalopram), trazodone, neuroleptics (eg, quetiapine), benzodiazepines. Beware of extrapyramidal side effects from neuroleptics.
Depression/anxiety	• Counseling • Art, music therapy	• SSRIs (eg, escitalopram and citalopram), SNRIs, mirtazapine, benzodiazepines
Dysphagia/malnutrition	• Periodic swallowing and body weight assessment • Ergonomic utensils • Oral hygiene care • Liquid thickener, chopped or pureed food, small meals • Diet adjusted to patient's preferences • Authors recommend avoiding feeding tubes in late stages with clear prion diagnosis.	• Glycopyrrolate or similar agents to decrease salivation if aspirating on saliva
Nausea/vomiting	• Adjust feeding amount and content. • Elevate bed. • Oral hygiene care	• Antiemetics, including serotonin 5-HT_3 receptor antagonists (eg, ondansetron) and prochlorperazine (caution for extrapyramidal side effects)
Insomnia	• Sleep hygiene • Regimented daily routine	• Melatonin, trazodone, mirtazapine, and quetiapine (latter mostly if agitation also an issue). Stronger agents might be needed for sporadic fatal insomnia or fatal familial insomnia.
Incontinence	• Regular bathroom schedules • Diapers • Condom catheter	• Consider various bladder agents, ideally those that are less anticholinergic.
Seizures	• Confirm seizures and not myoclonus.	• Antiepileptic agents, benzodiazepines
Visuospatial impairment/hemineglect	• Decrease the visuospatial complexity of environment. • Objects requiring attention presented at unaffected side or by moving around	

only open for U.K. citizens. As of October 2019, the sixth and final patient was treated, four of the patients had already died, and data was being analyzed to determine whether to move forward.

One of the more exciting developments in the treatment of neurologic and nonneurologic disorders has been the use of antisense oligonucleotides (ASOs) to block translation of messenger RNA and hence reduce production of specific proteins. ASOs are now in clinical practice for the treatment of at least three neurologic disorders, spinomuscular atrophy, Duchenne muscular dystrophy, and familial amyloid polyneuropathy and in phase 1 to 3 trials for several more disorders. There is some data to suggest that partial reduction of PrP^C should be safe in humans. Knockout mice for *PRNP* live a normal lifespan with only minor abnormalities detected. A few adults identified as *PRNP* hemizygous appear to be healthy. *PRNP* knockout mice are resistant to prions, and when mice hemizygous for *PRNP* (which have half the level of PrP^C) are inoculated with prions they have significantly increased survival. Thus, lowering of PrP^C levels may be a disease-modifying treatment for human prion disease, particularly if given prior to symptom onset, such as in carriers of *PRNP* mutations or persons exposed to prions. A recent study with ASOs targeted to reduce PrP^C (delivered via intracerebroventricular injection) in prion-infected wild-type mice showed prolonged survival when administered prophylactically prior to prion inoculation or even after infection but prior to symptom onset. ASOs may be effective in human prion diseases, particularly if used prophylactically. Such studies in humans are currently being planned. The coming decade should be an exciting one for improved understanding and treatment of human prion disease.

Primary and Secondary Headache Disorders 56

Peter J. Goadsby and Richard B. Lipton

KEY POINTS

1. Headache disorders, whether primary or secondary, share second-order trigeminocervical neurons as a final common sensory pathway, which can lead to symptom overlap. A careful history and examination is needed to differentiate them.
2. Secondary headache can herald a life-threating vascular or infectious condition, but are more commonly a manifestation of benign disorders such has a viral infection, the flu, a hangover, or mild head injury.
3. Migraine is the most common disabling primary headache and the most likely to be seen in the office practice of neurologists.
4. Trigeminal autonomic cephalalgias, particularly cluster headache, present with extremely severe, lateralized pain and associated symptoms needing rapid diagnosis and management.
5. Recent advances in the therapies of primary headache disorders, such as pathway specific treatments and neuromodulation approaches, are enriching disease understanding and making practice increasingly rewarding for patient and doctor.

ANATOMY AND PHYSIOLOGY OF HEADACHE

Headache is one of the most common clinical symptoms evaluated by neurologists and has a broad differential diagnosis. The successful management of both primary and secondary headache disorders requires an understanding of the relevant neuroanatomy and underlying physiology.

Pain in many settings is adaptive. It typically occurs when peripheral nociceptors are stimulated by factors such as tissue injury or visceral distension. In these settings, pain perception is a normal physiologic response mediated by a healthy nervous system. However, pain can also occur from damage, or inappropriate activation of pain-producing pathways of the peripheral or central nervous system. Headache may result from either, or both, of these mechanisms depending on the setting. The cranial pain-generating structures include the scalp, the falx cerebri, the dural sinuses, and the proximal segments of the large pial arteries. The majority of the brain parenchyma, ventricular ependyma, choroid plexus, and pial veins are not thought to be capable of producing pain.

The key structures involved in primary headache disorders include (Fig. 56.1)

- The large intracranial vessels, dura mater, and the peripheral terminals of the trigeminal nerve that innervate these structures
- The caudal portion of the trigeminal nucleus, which extends into the dorsal horns of the upper cervical spinal cord and receives input from the trigeminal nerve as well as the first and second cervical nerve roots: the trigeminocervical complex
- Rostral pain-processing regions, such as the ventroposteromedial thalamus and the cortex
- Pain modulatory systems in the brain that modulate input from trigeminal nociceptors at all levels of the pain-processing pathways and influence vegetative functions, such as hypothalamus and brainstem structures

The innervation of the large intracranial vessels and dura mater by the trigeminal nerve is referred to as the *trigeminovascular system*. Cranial autonomic symptoms, such as *lacrimation*, *conjunctival injection*, *nasal congestion*, *rhinorrhea*, *periorbital swelling*, *aural fullness*, and *ptosis*, are prominent in the trigeminal autonomic cephalalgias (TACs) and may also be seen in migraine. These autonomic symptoms result from activation of cranial parasympathetic pathways; functional imaging studies also suggest that vascular changes in migraine and cluster headache, when present, are driven by these cranial autonomic systems. When mistaken as evidence of sinus infection or inflammation, these symptoms may result in misdiagnosis and inappropriate management. Migraine and other primary headache syndromes are not primarily "vascular headaches" as was once thought; these disorders do not reliably demonstrate vascular changes, and treatment outcomes cannot be predicted by vascular effects. Migraine is fundamentally a brain disorder and should be understood and treated as such.

CLINICAL EVALUATION OF HEADACHE DISORDERS

The differential diagnosis of a new-onset, severe headache is quite different from that of a chronic, recurrent headache. There is a greater likelihood of finding a potentially serious underlying cause in a patient with new-onset and severe headache

FIGURE 56.1 Pathophysiology of migraine. Peripheral sensory inputs are conveyed via trigeminal afferents arising in the trigeminal ganglion (TG) to the trigeminocervical complex (TCC) that represents the main interface for trigeminal pain processing between the peripheral and central nervous systems. Projection neurons then ascend in the quintothalamic tract decussating in the brainstem, synapsing on thalamocortical relay neurons in multiple thalamic nuclei. Collateral ascending projections also target several nuclei, including the rostral ventromedial medulla (RVM), locus coeruleus (LC), periaqueductal grey (PAG), and hypothalamus. **A:** Thalamocortical relay neurons then convey the sensory information to multiple cortical regions. This trigeminal pain processing network receives descending modulatory inputs at several levels. **B:** At the level of the TCC, direct projections from multiple cortical regions and indirect projections via the hypothalamus, PAG, RVM, and LC exert potent modulatory effects on neuronal firing. **C:** The TCC receives its peripheral sensory inputs from primary afferents innervating the intracranial and extracranial structures of all three dermatomes of the head (mandibular [V3], maxillary [V2], and ophthalmic [V1]) as well as convergent inputs from the posterior dura and cervical dermatomes. In addition to the ascending trigeminothalamic projections from the TCC, a trigeminal-autonomic reflex exists between the trigeminal sensory afferents and the superior salivatory nucleus (SSN) that regulates parasympathetic outflow to the face via the sphenopalatine ganglion (SPG). The *dashed lines* represent the potential interfaces between the trigeminal and parasympathetic arms of the trigeminal-autonomic reflex that remain to be fully characterized. (*After* Goadsby PJ, Holland PR. An update: pathophysiology of migraine. *Neurol Clin*. 2019;37:651-671.)

than in a patient with similar headaches that have recurred over years. Life-threatening headache is relatively uncommon, but vigilance is required in order to recognize and appropriately treat such patients. Serious causes to be considered include meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, tumor, and purulent sinusitis. A classification system for headache disorders has been established by the International Headache Society—the International Classification of Headache Disorders, now in its third edition. The most recent version divides the disorders into *primary headaches*, in which the headache and associated features constitute the disorder itself, and *secondary headaches*, in which the headache results from exogenous causes.

SECONDARY HEADACHE

Chapter 9 presents an approach for identifying secondary headaches based on the identification of red flags, warning signals that suggest secondary headache. Figure 9.1 provides an algorithm for excluding secondary headache as a prelude to diagnosing primary headache disorders. Table 9.1 provides a list of red flags and the secondary headache disorders associated with those red flags. Table 9.2 summarizes worrisome clinical presentations and associated diagnostic possibilities. Although identifying secondary headaches is crucial, the vast majority of patients presenting with severe recurrent headache have a benign cause. The management of secondary headache focuses on diagnosis

and treatment of the underlying cause. In the following text we highlight a few important causes of secondary headache:

- **Meningitis:** Acute, severe headache with fever and stiff neck suggests meningitis (see Chapter 64). Often, there is significant worsening of pain with eye movement. Lumbar puncture is necessary for diagnosis. Meningitis can be easily mistaken for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are frequently present, perhaps reflecting an underlying biology in some of these cases.
- **Subarachnoid hemorrhage:** Acute, severe headache with stiff neck but without fever suggests subarachnoid hemorrhage (see Chapter 40). A ruptured aneurysm, arteriovenous malformation, or intraparenchymal hemorrhage may also present with headache alone. In rare cases (particularly if the hemorrhage is small or below the foramen magnum), head computed tomography can be normal. Thus, lumbar puncture may be required for definitive diagnosis of a subarachnoid hemorrhage.
- **Brain tumor:** Brain tumor is a rare cause of headache and even less commonly a cause of severe pain. The head pain is generally nondescript—an intermittent deep, dull ache of moderate intensity, which may worsen with exertion or change in position and may be associated with nausea and vomiting. Such symptoms are caused by migraine far more often than from brain tumor. The headache of brain tumor awakens patients from sleep in about 10% of cases. Vomiting that precedes the development of headache by weeks is highly characteristic of posterior fossa brain tumors. Head pain triggered by Valsalva maneuvers such as bending, lifting, or coughing can be due to a posterior fossa mass. De novo headache in a patient with known malignancy may suggest cerebral metastases and/or carcinomatous meningitis.
- **Giant cell arteritis (temporal arteritis):** Giant cell arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches, specifically the short posterior ciliary arteries. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of the disorder is important. Headache is the dominant symptom and often appears in association with malaise and myalgias. Head pain may be unilateral or bilateral and is located temporally in 50% of patients but may involve any and all aspects of the cranium. The quality is almost always described as dull and boring, with superimposed episodic stabbing pains and exquisite scalp tenderness. Patients often describe a superficial origin of their headache (external to the skull rather than originating deep within the head as in migraine). Headache is usually worse at night and often aggravated by exposure to cold. Additional findings may include reddened, tender nodules or red streaking of the skin overlying the temporal arteries and tenderness of the temporal or, less commonly, the occipital arteries. The management of temporal arteritis is further discussed in Chapter 43.
- **Glaucoma:** Glaucoma may present with a prostrating headache of sudden onset associated with nausea and vomiting. The headache often starts with severe eye pain. On physical examination, the eye is often red with a fixed, moderately dilated pupil. Patients may report seeing halos around brightly illuminated objects. Angle closure glaucoma requires prompt treatment.

PRIMARY HEADACHE DISORDERS

Primary headache disorders involve headache and associated features occurring in the absence of exogenous etiologies. The most common categories of primary headache are migraine, tension-type headache (TTH), and the TACs, notably cluster headache; the complete list is in **Table 56.1**. Each of these categories includes multiple related disorders, which may differ in prognosis and response to treatment. Chapter 9 presents an approach to primary headaches based on syndromes defined by attack frequency (<15 headache days per month and ≥15 headache days per month) and attack duration (<4 h and ≥4 h per attack). This syndromic approach defines four syndromes each with its own differential diagnosis. In the syndromic approach, episodic migraine falls into the episodic long duration group and chronic migraine falls into the chronic long duration group. In this chapter, we present primary headache disorders in groups defined by the International Classification of Headache Disorders, 3rd edition.

MIGRAINE

Epidemiology

Migraine is the most common disabling headache and ranks second on the list of world's most disabling disorders as measured by disability adjusted life years. Migraine afflicts 12% to 15 % of the population, more than 1 billion people globally. It is 3 times more common in women than in men and most common between the ages of 25 and 55 years. Migraine is characterized by recurring episodes of headache pain and associated neurologic dysfunction, manifested as sensitivity to sensory stimuli (light, sound, smell, or movement); nausea and vomiting often accompany the headache.

The migraine brain is particularly sensitive to environmental and sensory stimuli; migraine-prone patients do not habituate easily to sensory input. Headache can be initiated or amplified by various triggers, including bright lights, sounds, smells, or other afferent stimulation; hunger; stress or the letdown from stress; physical exertion; stormy weather, altitude, or barometric pressure changes; hormonal fluctuations during menses; lack of or excess sleep; and alcohol or other chemicals, such as nitrates. Identifying a patient's susceptibility to specific triggers, and sign-posting symptoms occurring in the premonitory phase, can be useful in advising lifestyle adjustments as part of the treatment plan.

Pathophysiology

The sensory sensitivity that is characteristic of migraine is due, in part, to dysfunction of monoaminergic sensory control systems located in the brainstem and diencephalon. Activation of cells in the trigeminal nucleus results in the release of vasoactive neuropeptides, particularly calcitonin gene–related peptide (CGRP), at vascular terminations of the trigeminal nerve and within the trigeminal nucleus. Centrally, second-order trigeminal neurons cross the midline and project to ventrobasal and posterior nuclei of the thalamus for further processing. There are additional projections to the periaqueductal gray, parabrachial nucleus, and hypothalamus, from which reciprocal descending systems have established

TABLE 56.1 Primary Headache Disorders[a]

Migraine	■ *Migraine without aura* ■ *Migraine with aura* • Migraine with typical aura • Typical aura with headache • Typical aura without headache • Migraine with brainstem aura • Hemiplegic migraine • Familial hemiplegic migraine (FHM) • Familial hemiplegic migraine type 1 • Familial hemiplegic migraine type 2 • Familial hemiplegic migraine type 3 • Sporadic hemiplegic migraine • Retinal migraine ■ *Chronic migraine* ■ *Complications of migraine* • Status migrainosus • Persistent aura without infarction • Migrainous infarction • Migraine aura-triggered seizure ■ *Probable migraine* • Probable migraine without aura • Probable migraine with aura ■ *Episodic syndromes that may be associated with migraine* • Recurrent gastrointestinal disturbance • Cyclical vomiting syndrome • Abdominal migraine • Benign paroxysmal vertigo • Benign paroxysmal torticollis
Tension-type headache	■ *Infrequent episodic tension-type headache* ■ *Frequent episodic tension-type headache* ■ *Chronic tension-type headache*
Trigeminal autonomic cephalalgias	■ *Cluster headache* • Episodic cluster headache • Chronic cluster headache ■ *Paroxysmal hemicrania* • Episodic paroxysmal hemicrania • Chronic paroxysmal hemicrania ■ *Short-lasting unilateral neuralgiform headache attacks* • Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) • Short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) ■ *Hemicrania continua*
Other primary headache disorders	■ *Primary cough headache* ■ *Primary exercise headache* ■ *Primary headache associated with sexual activity* ■ *Primary thunderclap headache* ■ *Cold-stimulus headache* • Headache attributed to external application of a cold stimulus • Headache attributed to ingestion or inhalation of a cold stimulus ■ *External-pressure headache* • External-compression headache • External-traction headache ■ *Primary stabbing headache* ■ *Nummular headache* ■ *Hypnic headache* ■ *New daily persistent headache (NDPH)*

antinociceptive effects. Other brainstem regions likely to be involved in descending modulation of trigeminal pain include the nucleus locus coeruleus in the pons and the rostroventromedial medulla.

Pharmacologic and other data implicate the involvement of the neurotransmitter 5-hydroxytryptamine (5-HT or serotonin) in migraine. The *triptans*, a widely used class of acute treatments, were designed to selectively stimulate subpopulations of 5-HT receptors; at least 14 different 5-HT receptors have been identified in humans. The triptans are potent 5-HT_{1B} and 5-HT_{1D} receptor agonists, and some are active at the 5-HT_{1F} receptor. Specific agonists of the 5-HT_{1F} receptor are called *ditans*. Triptans arrest nerve signaling in the nociceptive pathways of the trigeminovascular system, at least in the trigeminal nucleus caudalis and trigeminal sensory thalamus, through 5-HT_{1D} effects, and cause cranial vasoconstriction through 5-HT_{1B} effects. *Ditans*, specifically lasmiditan, are for the treatment of acute migraine, acting only at neuronal targets and do not cause vasoconstriction. An interesting range of neural targets is now being actively pursed for the acute and preventive management of migraine.

Data also support a role for dopamine in the pathophysiology of migraine. The majority of migraine symptoms can be induced by dopaminergic stimulation. Moreover, there is dopamine receptor hypersensitivity in migraineurs, as demonstrated by the induction of yawning, nausea, vomiting, hypotension, and other symptoms of a migraine attack by dopaminergic agonists at doses that do not affect nonmigraineurs. Dopamine receptor antagonists are effective therapeutic agents in migraine, especially when given parenterally or concurrently with other antimigraine agents. Importantly, hypothalamic activation, anterior to that seen in cluster headache, has now been shown in the premonitory phase of migraine using functional imaging and this may hold a key to understanding some part of the role of dopamine in the disorder.

Migraine genes have been identified by studying families with familial hemiplegic migraine (FHM) and reveal involvement of ion channels, suggesting that alterations in membrane excitability can predispose to migraine. Mutations involving the $Ca_v2.1$ (P/Q)-type voltage-gated calcium channel *CACNA1A* gene are now known to cause FHM-1; this mutation is responsible for about 50% of cases of FHM. Mutations in the Na^+-K^+ adenosine triphosphatase *ATP1A2* gene, designated FHM-2, are responsible for about 20% of FHM. Mutations in the neuronal voltage-gated sodium channel *SCN1A* cause FHM-3. Genome-wide association studies have identified at least 38 genomic loci that influence migraine risk, with a polygenic basis for the inheritance seeming most likely for the majority of patients.

Diagnosis and Clinical Features

Diagnostic criteria for migraine headache are summarized in Table 56.2. Migraine has several forms that are distinguished by the presence or absence of aura (migraine with and without aura) or by the number of monthly headache days (episodic migraine and chronic migraine) (see Table 56.1). The migraine aura is characterized by focal neurologic symptoms that evolve slowly and often involve a mix of positive and negative features. Visual aura is most common and may include positive features such as flashing lights or zigzag lines that move across the visual field, as well as negative features, such as a graying out of vision

TABLE 56.2 Simplified Diagnostic Criteria for Migraine[a]

Repeated attacks of headache lasting 4-72 h in patients with a normal physical examination, no other reasonable cause for the headache, and

At Least Two of the Following Features	Plus at Least One of the Following Features
Unilateral pain	Nausea/vomiting
Throbbing pain	Photophobia and phonophobia
Aggravation by movement	
Moderate or severe intensity	

[a]Adapted from Headache Classification Committee of the International Headache Society (IHS). The International Classification of Headache Disorders, 3rd edition. *Cephalalgia*. 2018;38:1-211.

(a scotoma). For sensory aura, the positive features include tingling and the negative features include numbness. Other aura types are described in the following text. Aura is reported in only 20% to 25% of patients with migraine. Visual aura should be distinguished from visual snow syndrome, which presents with pan-field continuous movement of uncountable dots. Visual snow does not have the evolution or the mix of positive and negative features that typify migraine aura. Patients with migraine-like headache at least 8 days per month and headache on at least 15 days per month are considered to have chronic migraine. Most patients with disabling headache likely have migraine, as opposed to TTH, which is the most common primary headache disorder (discussed later in this chapter).

Migraine aura has a range of manifestations other than the visual and sensory aura described above. Vertigo can be prominent; it has been estimated that one-third of patients referred for vertigo or dizziness have a primary diagnosis of migraine. Migraine aura can have prominent brainstem symptoms (such as diplopia, ataxia, altered consciousness, dysarthria, tinnitus, and vertigo), and the terms *basilar artery* and *basilar-type migraine* have now been replaced by *migraine with brainstem aura* (see **Table 56.1**). In hemiplegic migraine, the aura may have motor manifestations; in FHM, there is autosomal dominant transmission related to a number of genetic variants discussed above. Patients with acephalgic migraine (typical aura without headache) experience recurrent neurologic symptoms, frequently with nausea or vomiting, but with little or no headache.

Treatment of Migraine

Once a diagnosis of migraine has been established, it is important to assess the extent of a patient's disease and level of functional impairment. The Migraine Disability Assessment Score is a well-validated, easy-to-use tool. A headache diary also helps assess disability as well as the frequency of abortive medication use. Patient education is an important aspect of migraine management. It is useful for patients to understand that migraine is an inherited vulnerability for head pain and associated neurologic symptoms and that although the disorder cannot be "cured," migraine can be modified and managed by lifestyle adjustments and medications. Furthermore, patients should be reassured that migraine is generally not associated with serious or life-threatening illnesses. In patients who have migraine with aura, there is an increased risk of stroke, myocardial infarction, and all-cause cardiovascular mortality, although the absolute risk of these events is low.

Trigger and Lifestyle Approaches to Management

Migraineurs may benefit by identifying and avoiding specific headache triggers. A regulated lifestyle is important, including a healthy diet (with a regular eating schedule), exercise, routinized sleep patterns, avoidance of excess caffeine and alcohol, and minimizing acute changes in stress levels (such as through biofeedback, meditation, or yoga). Lifestyle modifications that are effective in reducing headache frequency should be maintained on a routine basis because these provide a simple, cost-effective approach to migraine management. If these measures fail to prevent an attack, abortive pharmacologic measures are then needed.

Acute Therapies

Table 56.3 summarizes the commonly used approaches for acute treatment of migraine, which include the nonsteroidal anti-inflammatory drugs (NSAIDs), 5-$HT_{1B/1D}$ receptor agonists (triptans), dihydroergotamine, selective 5-HT_{1F} receptor agonists (ditans), CGRP receptor antagonists (gepants), and dopamine receptor antagonists and neuromodulation devices [LEVEL 2].[1-29] Selecting the optimal regimen for an individual patient depends on several factors, the most important of which is the severity of the attack. Mild migraine attacks can usually be managed by oral agents, with an average efficacy rate of 50% to 70%. Severe migraine attacks may require intranasal or parenteral treatments for faster onset. In general, an adequate dose of the selected medication should be used as soon as possible after the onset of an attack. If additional medication is required within 1 hour due to persistence or recurrence of symptoms, the initial dose should be increased or a different class of rescue therapy should be taken. Migraine therapy must be individualized; a standardized approach for all patients is not feasible. Furthermore, a treatment regimen may need to be frequently revised until a successful plan is reached that provides rapid, complete, and consistent relief with minimal side effects (**Table 56.4**).

Nonsteroidal Anti-inflammatory Drugs

NSAIDs can significantly reduce the severity and duration of a migraine attack and are most effective when taken early in the attack. However, these agents alone may not completely abort a moderate or severe migraine attack. The combination of aspirin and metoclopramide has been shown to be comparable to a single dose of oral sumatriptan. Important side effects of NSAIDs include dyspepsia and gastrointestinal irritation as well as potential cardiovascular and renal effects (particularly with frequent or long-term use).

5-Hydroxytryptamine$_{1B/1D}$ Receptor Agonists (Triptans) and Ergots

Stimulation of 5-$HT_{1B/1D}$ receptors can abort an acute migraine attack. Ergotamine and dihydroergotamine are nonselective receptor agonists, whereas the triptans are selective 5-$HT_{1B/1D}$ receptor agonists. A variety of triptans, 5-$HT_{1B/1D}$ receptor agonists—almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan—are available for the acute treatment of migraine. Each drug in the triptan class has similar pharmacologic properties yet varies slightly in terms of clinical efficacy. Rizatriptan and eletriptan are the most likely to be efficacious. Sumatriptan and zolmitriptan have similar rates of efficacy as well as time to onset, with an advantage of having different routes of administration. Almotriptan has a similar

TABLE 56.3 Acute Treatment of Migraine Attacks[a]

Drug	Trade Name	Dosage
NSAIDs		
Naproxen[b]	Aleve, Anaprox, generic	220-550 mg orally twice a day
Ibuprofen[b]	Advil, Motrin, Nuprin, generic	400-800 mg orally q6-8h
Acetylsalicylic acid[b]	Aspirin, generic	500-1,000 mg orally twice a day
Tolfenamic acid	Clotam Rapid	200 mg orally; may repeat × 1 after 1-2 h
Diclofenac potassium[b]	Cambia, generic	50 mg orally with water
Compound Analgesics		
Acetaminophen, aspirin, caffeine[b]	Excedrin Migraine	Two tablets or caplets q6h (max 8 per day)
Migraine Specific: Triptans: 5-$HT_{1B/1D}$ Receptor Agonists		
Oral		
Naratriptan[b]	Amerge, generic	2.5-mg tablet at onset; may repeat once after 4 h
Rizatriptan[b]	Maxalt, generic Maxalt-MLT	5- to 10-mg tablet at onset; may repeat after 2 h (max 30 mg/d)
Sumatriptan[b]	Imitrex, generic	50- to 100-mg tablet at onset; may repeat after 2 h (max 200 mg/d)
Frovatriptan[b]	Frova	2.5-mg tablet at onset; may repeat after 2 h (max 5 mg/d)
Almotriptan[b]	Axert	6.25- to 12.5-mg tablet at onset; may repeat after 2 h (max 25 mg/d)
Eletriptan[b]	Relpax	20- to 40-mg mg tablet at onset (max 80 mg/d)
Zolmitriptan[b]	Zomig, generic Zomig Rapimelt	2.5- to 5-mg tablet at onset; may repeat after 2 h (max 10 mg/d)
Nasal		
Dihydroergotamine[b]	Migranal nasal spray	Prior to nasal spray, the pump must be primed four times; one spray (0.5 mg) is administered, followed in 15 min by a second spray.
Sumatriptan[b]	Imitrex nasal spray	5- to 20-mg intranasal spray as four sprays of 5 mg or a single 20-mg spray (may repeat once after 2 h, not to exceed a dose of 40 mg/d)
Zolmitriptan[b]	Zomig	2.5- to 5-mg intranasal spray as one spray (may repeat once after 2 h, not to exceed a dose of 10 mg/d)
Parenteral		
Dihydroergotamine[b]	D.H.E. 45	1 mg IV, IM, or SC at onset and q1h (max 3 mg/d, 6 mg/wk)
Sumatriptan[b]	Imitrex injection, generic Alsuma Sumavel DosePro	6 mg SC at onset (may repeat once after 1 h for max of two doses in 24 h)
Ditans: 5-HT_{1F} Receptor Agonists		
Lasmiditan	Reyvow	50, 100, or 200 mg taken orally
Gepants: CGRP Receptor Antagonists		
Rimegepant	Nurtec	75 mg taken orally
Ubrogepant	Ubrelvy	50 or 100 mg taken orally
Dopamine Receptor Antagonist		
Oral		
Metoclopramide	Reglan,[c] generic[c]	5-10 mg/d
Prochlorperazine	Compazine,[c] generic[c]	1-25 mg/d
Promethazine	Phenergan,[c] generic[c]	25-50 mg/d
Chlorpromazine	Thorazine,[c] generic[c]	25-50 mg/d
Parenteral		
Metoclopramide[b]	Reglan,[c] generic	10 mg IV
Prochlorperazine[b]	Compazine,[c] generic[c]	10 mg IV
Chlorpromazine[b]	Thorazine,[c] generic[c]	12.5-25 mg IM or IV (0.1 mg/kg IV at 2 mg/min)
Promethazine	Phenergan,[c] generic[c]	12.5-25 mg IM or IV (slow)

(table continues on page 527)

TABLE 56.3 Acute Treatment of Migraine Attacks[a] *(continued)*

Drug	Trade Name	Dosage
Neuromodulation		
Transcutaneous supraorbital nerve stimulation	Cefaly	Stimulate for 60 min.
sTMS	sTMS mini	Three pulses repeated if no initial response
Noninvasive vagus nerve stimulation	Gammacore	1-2 120 s stimuli to affected side
Remote electrical neuromodulation	Nerivio Migra	45-min stimulation on the upper arm

Abbreviations: 5-HT, 5-hydroxytryptamine; CGRP, calcitonin gene–related peptide; IM, intramuscular; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs; SC, subcutaneous; sTMS, single pulse transcranial magnetic stimulation.
[a]Antiemetics (eg, domperidone 10 mg or ondansetron 4 or 8 mg) or prokinetics (eg, metoclopramide 10 mg) are sometimes useful adjuncts.
[b]Supported by level 1 evidence.
[c]Not all drugs are specifically indicated by the U.S. Food and Drug Administration for migraine. Local regulations and guidelines should be consulted.

rate of efficacy to sumatriptan but is better tolerated, whereas frovatriptan and naratriptan are somewhat slower in onset yet have milder side effect profiles. Clinical efficacy appears to be related more to the t_{max} (time to peak plasma level) than to the potency, half-life, or bioavailability. This observation is consistent with various studies indicating that faster acting analgesics are more effective than slower acting agents.

TABLE 56.4 Clinical Stratification of Acute Specific Migraine Treatments

Clinical Situation	Treatment Options
Failed NSAIDs/simple analgesics	**First tier** Sumatriptan 50-100 mg orally Almotriptan 12.5 mg orally Rizatriptan 10 mg orally Eletriptan 40 mg orally Zolmitriptan 5 mg orally **Slower effect/better tolerability** Naratriptan 2.5 mg orally Frovatriptan 2.5 mg orally **Newer alternatives** Lasmiditan Rimegepant Ubrogepant
Early nausea or difficulty taking tablets	Zolmitriptan 5 mg nasal spray Sumatriptan 20 mg nasal spray Rizatriptan 10 mg MLT wafer Zolmitriptan 5 mg ZMT Rapimelt
Early vomiting	Zolmitriptan 5 mg nasal spray Sumatriptan 6 mg SC
Headache recurrence	Naratriptan 2.5 mg orally Almotriptan 12.5 mg orally Eletriptan 40 mg orally Frovatriptan Rimegepant Ubrogepant
Tolerating acute treatments poorly due to side effects	Naratriptan 2.5 mg orally Almotriptan 12.5 mg orally Lasmiditan Rimegepant Ubrogepant
Menstrual-associated headache	Frovatriptan 2.5 mg with Naprosyn 500 mg around menses
Rapidly developing symptoms	Zolmitriptan 5 mg nasal spray Sumatriptan 6 mg SC Dihydroergotamine 1 mg IM

Abbreviations: IM, intramuscular; NSAIDs, nonsteroidal anti-inflammatory drugs; SC, subcutaneous.

Unfortunately, monotherapy with oral triptan therapy does not yield rapid, consistent, and complete relief of migraine in all patients. Triptans may not be effective in migraine with aura unless taken after completion of the aura and initiation of the headache; recurrence of headache is another limitation of triptan use. Evidence from randomized controlled trials demonstrates that coadministration of a longer acting NSAID (such as naproxen 500 mg) with sumatriptan will augment the initial effect of sumatriptan and, importantly, reduce rates of headache recurrence. Side effects of triptans include nausea, chest tightness, dizziness, asthenia, and flushing. 5-$HT_{1B/1D}$ receptor agonists are contraindicated in individuals with a history of cardiovascular or cerebrovascular disease. In addition, there are precautions in labeling for individuals with multiple cardiovascular risk factors. In practice, rates of vascular events following triptan administration have been very low.

Nasal formulations of dihydroergotamine, zolmitriptan, or sumatriptan can, particularly with the addition of a permeation enhancer, be useful in patients requiring a nonoral route of administration (eg, due to nausea/vomiting). Intranasal administration can result in substantial blood levels within 30 to 60 minutes. Although nasal sprays in theory might provide faster and more effective relief than oral formulations, their reported efficacy is only 50% to 60%. Studies with a new inhalational formulation of dihydroergotamine indicate that its absorption problems can be overcome to produce rapid onset of action with good tolerability. Orally dissolving formulations of rizatriptan and zolmitriptan are convenient because no water is needed and may be less likely to induce nausea.

Sumatriptan and dihydroergotamine are also available in injection formulations. Sumatriptan 4 to 6 mg subcutaneously (SC) is effective in approximately 50% to 80% of patients. Peak plasma levels of dihydroergotamine are achieved 3 minutes after intravenous dosing, 30 minutes after intramuscular dosing, and 45 minutes after SC dosing. If an attack has not already reached peak, SC or intramuscular administration of 1-mg dihydroergotamine can be effective in about 80% to 90% of patients.

Dopamine Receptor Antagonists

Oral dopamine receptor antagonists can be considered as adjunctive acute migraine treatments. Drug absorption is impaired during migraine due to reduced gastrointestinal motility (even in the absence of nausea) and is related to the severity of the attack rather than duration. Therefore, when oral NSAIDs and/or triptans fail, the addition of an oral dopamine receptor antagonist (such as metoclopramide 10 mg) should be considered

to enhance gastric absorption as well as to decrease nausea/vomiting. Certain dopamine blockers such as metoclopramide, and some phenothiazine drugs (such as promethazine, prochlorperazine, or chlorpromazine), can also independently improve headache pain, particularly when given parenterally, although akathisia, sedation, and orthostatic hypotension may limit use.

Ditans: 5-HT_{1F} Receptor Agonists

Ditans are centrally penetrant, neurally active acute treatments of migraine with no vasoconstrictor lability. One is currently available, lasmiditan, which was more effective than placebo at 2 hours in rendering patients pain free and most bothersome symptom free when administered orally. Dizziness occurs in about 15% of patients, and it is advised that patients do not drive for 8 hours after taking the medicine. Because ditans do not cause vasoconstriction, they offer an effective and safe option in patients with vascular contraindications to triptans.

Gepants: Calcitonin Gene–Related Peptide Receptor Antagonists

Gepants are orally active small molecule CGRP receptor antagonists available for the acute treatment. Both ubrogepant and rimegepant were more effective than placebo at 2 hours in rendering patients pain free and most bothersome symptom free. Ubrogepant is available in 50 or 100 mg tablets. Rimegepant is being marketed as a 75-mg orally dissolving tablet. Both drugs are extremely well tolerated with only mild side effects in less than 5% of patients. Apart from avoiding ubrogepant with strong CYP3A4 inhibitors, they are easy to use and effective medicines. Broadly, acute gepants will likely be most useful in patients who do not respond to or cannot tolerate triptans, and in patients with cardiovascular contraindications to triptans. Because oral gepants are being developed as preventive treatments (see in the following text), and because frequent use of rimegepant as an acute treatment is associated with a reduction in monthly migraine days, it is hoped that this class, unlike the triptans and combination analgesics, will not cause medication overuse. A nasal spray formulation of a gepant, vazegepant, is in development.

Other Medications for Acute Migraine

Opioids are modestly effective in the acute treatment of migraine and are commonly administered in the emergency room. Such agents can "help" in the sense that the pain of migraine is eliminated or reduced. However, this regimen is suboptimal for patients with recurrent headache. Opioids do not treat the underlying headache pathophysiology; rather, they act to alter the sensation of pain, and there is evidence that they can render other migraine medications (such as triptans) less effective. Moreover, frequent opioid use can result in medication overuse headache as well as physical dependence or addiction; opioid craving and/or withdrawal can in turn worsen migraine. Therefore, it is recommended that opioid use in migraine be restricted to patients with severe, but infrequent, headaches that are unresponsive to other pharmacologic approaches or who have contraindications to other treatments.

Butalbital-containing compounds are also frequently given for acute migraine treatment. Although these medications may provide analgesic relief, there is a high potential for dependence and the development of medication overuse headache (also known as *rebound headache*), which is a state of refractory daily or near-daily headache. This condition is likely not a separate headache entity but a reaction of the migraine patient to a particular medicine. Butalbital-containing medications have been banned in some countries and, although still available in the United States, should be avoided.

Neuromodulation Approaches to Acute Therapy

Transcutaneous supraorbital nerve stimulation, single pulse transcranial magnetic stimulation (sTMS), noninvasive vagus nerve stimulation, and remote electrical neuromodulation have all been shown to have some benefit in the acute treatment of migraine. In females considering pregnancy, sTMS is particularly attractive given what is known about the low birth risks with magnetic resonance imaging (MRI).

Preventive Treatments for Migraine

Patients who experience an increasing frequency of migraine attacks, or attacks that are poorly responsive to acute medications, warrant preventive therapy. In general, preventive treatments should be considered for patients with four or more migraine days a month; however, the decision of when to start a preventive agent may also depend on the severity and duration of attacks, response to acute therapy, and patient preference. Many preventive medications have significant side effects, and the therapeutic dose can vary significantly among individual patients. The mechanism of action of these drugs is not entirely known; it is likely that they modify the brain sensitivity that underlies migraine. For oral preventive medications, patients are usually started on a low dose, which is gradually titrated up to a reasonable target dose. Oral preventive medication must be taken daily, and there is usually a lag of 2 to 12 weeks before benefits occur.

Commonly used preventive medications for migraine are listed by class in **Table 56.5** LEVEL 7.[30-65] The oral drugs that have been approved by the U.S. Food and Drug Administration for the preventive treatment of migraine include two β-blockers (propranolol, timolol) and two anti-epilepsy drugs (sodium valproate and topiramate). In addition, a number of other drugs appear to display preventive efficacy. This includes amitriptyline, nortriptyline, candesartan, flunarizine, phenelzine, gabapentin, and cyproheptadine. Onabotulinum toxin type A has been shown to be effective in placebo-controlled studies for the prevention of chronic migraine but not of episodic migraine. The probability of success with any one of these medications is approximately 50%.

Once effective stabilization is achieved, the drug is continued for approximately 6 to 12 months and then slowly tapered to assess whether continuation is needed. Many patients are able to wean off prophylactic medications successfully, with fewer and milder attacks for long periods. This may suggest that treatment alters the natural history of disease, although there are other possibilities. The newest edition to therapeutic options for migraine prevention target the CGRP pathway.

Monoclonal Antibodies

Given the role of CGRP in migraine pathophysiology, monoclonal antibodies have been developed to either the CGRP peptide (eptinezumab, fremanezumab and galcanezumab), or to the canonical CGRP receptor (erenumab). These medicines are each effective in the preventive treatment of migraine. Patients with episodic migraine, 4 to 14 days a month, or chronic migraine, ≥15 days a month, have reduced migraine frequency with these medicines versus placebo. They are given either monthly SC, or quarterly, SC or intravenously. They are well tolerated and, in prospective randomized placebo controlled trials, are effective in patients who have failed up to four preventives.

Monoclonal antibodies, as a group, are recommended for patients who do not respond to, or who cannot tolerate oral generic

TABLE 56.5 Preventive Treatments in Migraine[a]

Drug	Dose	Selected Side Effects
β-Blockers		Fatigue, postural symptoms, bradycardia, depression, nightmares
Propranolol[b]	40-120 mg twice a day	Caution in patients with asthma
Metoprolol[b]	25-100 mg twice a day	—
Timolol[b]	5-10 mg twice a day	—
Atenolol	25-100 mg every day	—
Nadolol	40-240 mg divided twice or 3 times a day	—
Anticonvulsants		
Topiramate[b]	25-200 mg/d	Paresthesias, cognitive impairment, weight loss, nausea, fatigue, glaucoma, and metabolic acidosis; caution with nephrolithiasis
Valproate[b]	400-600 mg twice a day	Drowsiness, weight gain, hair loss, tremor, hematologic or liver abnormalities, fetal abnormalities
Gabapentin	900-3,600 mg every day	Dizziness, sedation, weight gain
Antidepressants		
Amitriptyline	10-100 mg at night	Drowsiness, dry mouth, constipation, blurred vision, postural hypotension, weight gain
Nortriptyline	10-100 mg at night	***Note:*** Some patients may only need a total dose of 10 mg, although generally, 1-1.5 mg/kg body weight is required.
Doxepin	10-75 mg at night	Sedation, dry mouth, weight gain
Venlafaxine[b]	75-150 mg every day	Nausea, insomnia, dizziness, fatigue, nervousness
Serotonergic Drugs		
Pizotifen[c]	0.5-2 mg every day	Weight gain, drowsiness
CGRP Pathway Monoclonal Antibodies		
Eptinezumab (Vyepti)	100 or 300 mg IV quarterly	—
Erenumab (Aimovig)	70 or 140 mg SC monthly	—
Fremanezumab (Ajovy)	225 mg SC monthly or 675 mg SC quarterly	—
Galcanezumab (Emgality)	240 mg SC loading dose then 120 mg SC monthly	—
Neuromodulation		
sTMS	sTMS mini	2-8 pulses 2 to 3 times daily
Transcutaneous supraorbital nerve stimulation	Cefaly	Stimulate 20 min daily
Other Classes		
Flunarizine[c] (calcium channel blocker)	5-15 mg every day	Drowsiness, weight gain, depression, parkinsonism
Candesartan (ARB inhibitor)	16 mg every day	Dizziness, hypotension
Onabotulinum toxin type A[b] (Botox)	155 units divided in 31 sites (PREEMPT protocol)	Loss of brow furrow, ptosis, pain at injection sites, neck stiffness
Complementary Agents		
Petasites (butterbur)[b]	75 mg twice a day	Stomach upset
Riboflavin (vitamin B_2)	400 mg every day	Urine discoloration
Magnesium	500-600 mg every day	Increased bowel motility
Feverfew (MIG-99)	6.25 mg 3 times a day	Stomach upset, nausea

Abbreviations: ARB, angiotensin II receptor blocker; CGRP, calcitonin gene–related peptide; IV, intravenous; PREEMPT, Phase III Research Evaluating Migraine Prophylaxis Therapy protocol; sTMS, single pulse transcranial magnetic stimulation.

[a]Commonly used preventives are listed with typical doses and common side effects. Not all listed medicines are approved by the U.S. Food and Drug Administration; local regulations and guidelines should be consulted.

[c]Not available in the United States.

preventive medications. They have a number of advantages over oral generic preventive medications. First, dose titration is not necessary; the initial dose is often the optimal dose. Secondly, therapeutic benefits develop relatively rapidly with statistically significant reduction in migraine days in the first week following administration. Full benefits sometimes develop more slowly, over several months. Thirdly, these agents are very well tolerated relative to oral preventives; and finally, with infrequent dosing, adherence is easier than with the daily oral generics.

Gepants as Preventives

Given the success of CGRP pathway monoclonal antibodies, and the outcome of an initial clinical trial with a gepant, these medicines are being developed as preventives. Two are in clinical development: atogepant with two positive phase 3 studies and rimegepant, currently under study.

Neuromodulation Approaches to Prevention

Neuromodulation with transcutaneous supraorbital nerve stimulation or sTMS have been shown to be effective in the preventive treatment of migraine. They are safe and extremely well tolerated approaches, particularly for patients in the reproductive years or who have had significant side effects with pharmacologic preventives.

TENSION-TYPE HEADACHE

Clinical Features

TTH is the most common primary headache disorder, although patients rarely present to the clinic due to the low level of associated disability. TTH is characterized by bilateral tight, band-like head discomfort of mild to moderate severity. The pain usually progresses slowly, fluctuates in severity, and may persist more or less continuously for many days. The headache may be episodic or chronic (present on 15 or more days per month). Unlike migraine, TTH is otherwise featureless and lacks accompanying features such as nausea, vomiting, photophobia, phonophobia, osmophobia, throbbing, and aggravation with movement.

Pathophysiology

The pathophysiology of TTH is incompletely understood. It seems likely that TTH is due to a primary disorder of central nervous system pain modulation alone, unlike migraine, which involves a more generalized disturbance of sensory modulation. Data suggest a genetic contribution to TTH, although this may not be a valid finding, as these studies likely included many migraine patients. The name *tension-type headache* implies that pain is a product of *nervous tension*; however, there is no clear evidence for tension as an etiology. Muscle contraction has been considered to be a feature that distinguishes TTH from migraine, but there appear to be no differences in electromyogram activity between the two headache types.

Treatment

The pain of TTH usually responds to simple analgesics such as acetaminophen, aspirin, or other NSAIDs. Behavioral approaches including relaxation can also be effective. Clinical studies have demonstrated that triptans in pure TTH are not helpful, although triptans are effective in TTH when the patient also has migraine. For chronic TTH, amitriptyline (10-100 mg/d) is the only proven treatment; other tricyclics, selective serotonin reuptake inhibitors, and the benzodiazepines have not been shown to be effective. There is no evidence for the efficacy of acupuncture. Placebo-controlled trials of onabotulinum toxin type A in chronic TTH have been negative.

TRIGEMINAL AUTONOMIC CEPHALALGIAS

The TACs describe a group of primary headaches including cluster headache, paroxysmal hemicrania (PH), short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT)/short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA), and hemicrania continua (HC) (see Table 56.1). The TACs are characterized by relatively short-lasting attacks of head pain in the first division of the trigeminal nerve (hence trigeminal in the name) associated with cranial autonomic symptoms, such as lacrimation, conjunctival injection, or nasal congestion (Table 56.6). Pain is usually severe and may occur more than once a day. Because of the associated nasal congestion or rhinorrhea, patients are often misdiagnosed with "sinus headache" and treated with decongestants, which are ineffective. The key feature of this class of headaches is the lateralized nature of symptoms (eg, side-locked head pain and ipsilateral cranial autonomic features).

TACs must be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia (TN), primary stabbing headache, and hypnic headache. The cycling pattern and length, frequency, and timing of attacks are useful in classifying patients. Patients with TACs should undergo pituitary imaging and pituitary function tests because there is an excess of TAC presentations in patients with pituitary tumor–related headache.

Cluster Headache

Clinical Features

Cluster headache is a rare primary headache syndrome with a population frequency of approximately 0.1%, affecting men more than women at a gender prevalence ratio of 3:1. The pain is deep, usually retro-orbital, often excruciating in intensity, nonfluctuating, and explosive in quality. A core feature of cluster headache is periodicity. At least one of the daily attacks of pain recurs at about the same hour each day for the duration of a cluster bout. Onset is nocturnal in about 50% of patients. The typical cluster headache patient has daily bouts of one or two attacks of relatively short-duration unilateral pain for 8 to 10 weeks a year; this is usually followed by a pain-free interval that averages a little less than 1 year. Cluster headache is characterized as chronic when attacks persist over for at least a year with less than 3 month of sustained remission without treatment. Patients with cluster headache tend to be restless during attacks and may pace, rock, or rub their head for relief; some may even become aggressive during attacks. This is in sharp contrast to patients with migraine who prefer to remain motionless during attacks.

Pathophysiology

Cluster headache is likely to be a disorder involving central pacemaker neurons in the posterior hypothalamic region, thus

TABLE 56.6 Clinical Features of the Trigeminal Autonomic Cephalalgias

	Cluster Headache	Paroxysmal Hemicrania	SUNCT/SUNA
Gender pain	M > F	F = M	F ~ M
Type	Stabbing, boring	Throbbing, boring, stabbing	Burning, stabbing, sharp
Severity	Excruciating	Excruciating	Severe to excruciating
Site	Orbit, temple	Orbit, temple	Periorbital
Attack frequency	1/alternate day to 8/d	1-20/d (>5/d for more than half the time)	3-200/d
Duration of attack	15-180 min	2-30 min	5-240 s
Autonomic features	Yes	Yes	Yes (prominent conjunctival injection and lacrimation)[a]
Migrainous features[b]	Yes	Yes	Yes
Alcohol trigger	Yes	No	No
Cutaneous triggers	No	No	Yes
Indomethacin effect	—	Yes[c]	—
Abortive treatment	Sumatriptan injection or nasal spray Zolmitriptan nasal spray Oxygen Noninvasive vagus nerve stimulation	No effective treatment	Lidocaine (IV)
Preventive treatment	Verapamil Lithium Galcanezumab	Indomethacin	Lamotrigine Topiramate Gabapentin

Abbreviations: F, female; IV, intravenous; M, male; SUNA, short-lasting unilateral neuralgiform headache attacks with cranial autonomic features; SUNCT, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing.
[a]If conjunctival injection and tearing not present, consider SUNA.
[b]Nausea, photophobia, or phonophobia; photophobia and phonophobia are typically unilateral on the side of the pain and seen in patients with a personal or family history of migraine.
[c]Indicates complete response to indomethacin.

accounting for its periodicity. Other hallmark features of cluster headache include the ipsilateral symptoms of cranial parasympathetic autonomic activation: conjunctival injection or lacrimation, rhinorrhea or nasal congestion, or cranial sympathetic dysfunction such as ptosis. The sympathetic deficit is peripheral and likely due to parasympathetic activation with injury to ascending sympathetic fibers surrounding a dilated carotid artery as it passes into the cranial cavity. When present, photophobia and phonophobia are far more likely to be unilateral and on the same side of the pain, rather than bilateral, as is seen in migraine. This phenomenon of unilateral photophobia/phonophobia is characteristic of TACs.

Treatment

As with migraine, there are both abortive (acute) medications and preventive therapies that can be used during a cluster bout LEVEL 2.[66-81]

Abortive Treatment

Cluster headache attacks peak rapidly, and thus, a treatment with quick onset is required. Many patients with acute cluster headache respond very well to oxygen inhalation. This should be given as 100% oxygen at 10 to 12 L/min for 15 to 20 minutes at the onset of the attack. Sumatriptan 6 mg SC is rapid in onset and will usually shorten an attack to 10 to 15 minutes; there is no evidence of tachyphylaxis. Sumatriptan (20 mg) and zolmitriptan (5 mg) nasal sprays are also both effective in acute cluster headache. Oral sumatriptan is not effective for either prevention or acute treatment of cluster headache. Noninvasive vagus nerve stimulation is effective in the treatment of attacks in episodic cluster headache, compared to sham, at 15 minutes, although not useful for attacks in patients with chronic cluster headache.

Preventive Treatments

Table 56.7 summarizes commonly used treatments for the prevention of cluster headache. The choice of a preventive treatment in cluster headache depends in part on the length of the bout. Patients with long bouts or those with chronic cluster headache

TABLE 56.7 Preventive Management of Cluster Headache

Short-Term Prevention	Long-Term Prevention
Episodic Cluster Headache	Episodic Cluster Headache and Prolonged Chronic Cluster Headache
Prednisone 1 mg/kg up to 60 mg every day, tapering over 21 d	Verapamil 160-960 mg/d *(immediate-release formulation, divided twice or 3 times a day)*
Verapamil 160-960 mg/d	Lithium 400-800 mg/d
Greater occipital nerve injection[a]	Topiramate[b] 100-400 mg/d
	Gabapentin[b] 1,200-3,600 mg/d
	Melatonin[b] 9-12 mg/d
Galcanezumab 300 mg SC monthly	Non-invasive vagus nerve stimulation

[a]Supported by level 1 evidence.
[b]Unproven but of potential benefit.

require medicines that are safe when taken for long periods. For patients with relatively short bouts, limited courses of oral glucocorticoids can be very useful. A 10-day course of prednisone, beginning at 60 mg daily for 7 days and followed by a rapid taper, can also help to interrupt the cycle. An alternative with controlled trial evidence is greater occipital nerve injection with a corticosteroid and a local anesthetic. Lithium (400-800 mg/d) appears to be particularly useful for the chronic form of the disorder. Noninvasive vagus nerve stimulation is effective compared to standard of care in the preventive treatment of chronic cluster headache. Melatonin and topiramate are used in the preventive treatment of cluster headache, although the evidence base is limited.

Many experts favor verapamil as the first-line preventive treatment for patients with chronic cluster headache or prolonged bouts. Although verapamil compares favorably with lithium in practice, some patients require verapamil doses far in excess of those administered for cardiac disorders. The initial dose range is 40 to 80 mg twice daily; effective doses may be as high as 960 mg/d. Side effects include constipation and lower extremity edema. Of greater concern is the cardiovascular safety of verapamil, particularly at high doses. Verapamil can induce heart block by slowing conduction in the atrioventricular node and thus requires close monitoring of the PR interval with serial electrocardiograms (ECGs). Approximately 20% of patients treated with verapamil develop ECG abnormalities, which can occur at doses as low as 240 mg/d; these abnormalities can worsen over time in patients on stable doses. A baseline ECG is recommended for all patients. The ECG is then repeated 10 days after a dose change in those patients whose dose is being increased above 240 mg daily. Dose increases are usually made in 80-mg increments. Patients on long-term verapamil should have ECG monitoring every 6 months.

Galcanezumab, a monoclonal antibody to CGRP, has been shown to be effective compared to placebo in reducing attacks in patients with episodic cluster headache. It did not have a demonstrable effect in chronic cluster headache.

Neurostimulation Therapy

When medical therapies fail in chronic cluster headache, neurostimulation strategies can be considered. There are two sham-controlled positive studies with sphenopalatine ganglion stimulation in the preventive treatment of chronic cluster headache. There is open-label experience with occipital nerve stimulation. Deep brain stimulation of the region of the posterior hypothalamic gray matter has proven successful in a substantial proportion of patients in open label use, although with its morbidity and possible mortality, and a negative controlled trial, it is not recommended prior to less invasive approaches.

Paroxysmal Hemicrania

PH is characterized by unilateral, severe, short-lasting attacks (2-45 min) of head pain that are frequent (more than five times per day). Like cluster headache, the pain tends to be retroorbital but also may be experienced in other regions of the head and is associated with ipsilateral cranial autonomic phenomena such as lacrimation and nasal congestion. However, unlike cluster headache, which predominantly affects males, the male-to-female ratio in PH is close to 1:1. Episodic PH is characterized by periods of remission, whereas the nonremitting form is termed *chronic PH*. PH is marked by an excellent response to indomethacin (25-75 mg three times a day), which can completely suppress attacks often within a few days of initiating the required dose. Although therapy may be complicated by indomethacin-induced gastrointestinal side effects, currently, there are no consistently effective alternatives. Noninvasive vagus nerve stimulation is useful in half of patients with PH. Topiramate (50-300 mg/d) has been reported to be helpful in some cases, as has piroxicam (20-40 mg/d), although not to the same extent as indomethacin. Verapamil, an effective treatment for cluster headache, does not appear to be useful for PH. In occasional patients, PH can coexist with TN (PH-tic syndrome); similar to cluster-tic syndrome, each component may require separate treatment.

Secondary PH has been reported from lesions in the region of the sella turcica, including arteriovenous malformation, cavernous sinus meningioma, pituitary pathology, and epidermoid tumors. Secondary PH is more likely if the patient requires high doses (>200 mg/d) of indomethacin. In patients with apparent bilateral PH, raised cerebrospinal fluid (CSF) pressure should be suspected. It is important to note that indomethacin reduces CSF pressure. When a diagnosis of PH is considered, as with other TACs, MRI is indicated to exclude a pituitary lesion.

SUNCT/SUNA

Clinical Features

SUNCT is a rare primary headache syndrome characterized by severe, unilateral orbital or temporal pain that is stabbing or throbbing in quality. Diagnosis requires at least 20 attacks, lasting for 5 to 240 seconds; ipsilateral conjunctival injection, and lacrimation should be present. In some patients, conjunctival injection or lacrimation is missing, and the diagnosis of SUNA can be made.

The pain of SUNCT/SUNA is unilateral and may be located anywhere in the head. Three basic patterns can be seen: *single stabs*, which are usually short lived; *groups of stabs*; or a longer attack consisting of many stabs between which the pain does not completely resolve, thus yielding a "*sawtooth*" *pattern* with attacks lasting many minutes. Each pattern may be seen in the context of an underlying continuous head pain. Characteristics that lead to a suspected diagnosis of SUNCT are the cutaneous (or other) triggerability of attacks, a lack of refractory period to triggering between attacks (to distinguish it from TN), and the lack of a response to indomethacin (to distinguish it from PH). Apart from trigeminal sensory disturbance, the neurologic examination is normal in primary SUNCT.

The diagnosis of SUNCT is often confused with TN particularly in first-division TN (as discussed in Chapter 57). Minimal or no cranial autonomic symptoms and a clear refractory period to triggering indicate a diagnosis of TN. Secondary SUNCT can be seen with posterior fossa or pituitary lesions. All patients with SUNCT/SUNA should be evaluated with pituitary function tests and a brain MRI with pituitary views.

Treatment

Abortive therapy is not practical in SUNCT/SUNA because the attacks are of such short duration. The main goal of treatment is long-term prevention to minimize disability. The most effective prophylactic medication is lamotrigine at doses of 200 to 400 mg/d. Topiramate (50-300 mg/d) and gabapentin (800-2,700 mg/d) may also be effective. Carbamazepine (400-600 mg/d) has been reported by some to be moderately helpful. Surgical approaches such as microvascular decompression or destructive trigeminal procedures are seldom useful and often cause long-term complications such as permanent numbness and anesthesia doloroso. Greater occipital nerve blocks may yield limited benefit in some patients. Occipital nerve stimulation is

probably helpful in a subgroup of patients with SUNCT/SUNA. For intractable cases, short-term prevention with intravenous lidocaine, which can arrest symptoms rapidly, can be useful.

Hemicrania Continua

The essential features of HC are moderate and continuous unilateral pain with superimposed exacerbations of severe pain, which may be associated with cranial autonomic features and photophobia/phonophobia on the affected side. The age of onset reported in the literature ranges from 11 to 58 years; women are affected twice as often as men. The cause is unknown, although as with other TAC syndromes, pituitary pathology has been associated with HC.

As with PH, definitive treatment is indomethacin (25-75 mg three times a day); other NSAIDs appear to be of little or no benefit. Indomethacin should be initiated at 25 mg orally three times a day and then increased to 50 mg three times a day if no effect, and further to 75 mg three times a day if needed. Up to 2 weeks at the maximal dose may be necessary to assess whether a dose has a useful effect. Noninvasive vagus nerve stimulation is useful in more than half of patients with HC. Topiramate can be helpful in some patients, as can greater occipital nerve blocks. Occipital nerve stimulation probably has a role in patients with HC who are unable to tolerate indomethacin.

OTHER PRIMARY HEADACHES

Primary Cough Headache

Primary cough headache is a generalized headache that begins suddenly, lasts for several minutes, sometimes up to a few hours, and is precipitated by Valsalva maneuver, with coughing the best known; it is preventable by avoiding coughing or other precipitating events, which can include sneezing, straining, laughing, or stooping. In all patients with this syndrome, serious etiologies must be excluded before a diagnosis of "benign" primary cough headache can be established (as discussed earlier in this chapter and also in Chapter 9). Benign cough headache can resemble benign exertional headache (in the following text), but patients with the former condition are typically older. Remarkably, Valsalva maneuver, in the context of sexual activity during orgasm in patients with primary cough headache, is generally not painful. This distinction is generally a sign of benignity.

Indomethacin 25 to 50 mg two to three times daily is the treatment of choice. Some patients with cough headache obtain complete cessation of their attacks with lumbar puncture; this is a simple option when compared to prolonged use of indomethacin, and it is effective in about one-third of patients. The mechanism of this response is unclear.

Primary Exertional Headache

Primary exertional headache (PEH) has features resembling both cough headache and migraine. It may be precipitated by any form of exercise and often has the pulsatile quality of migraine. The pain, which can last from 5 minutes to 24 hours, is bilateral and throbbing at onset; migrainous features may develop in patients susceptible to migraine. When seen, it tends to be shorter in adolescents. PEH can be prevented by avoiding excessive exertion, particularly in hot weather or at high altitude. As with primary cough headache, exertion in the context of sexual activity generally does not trigger headache in patients with PEH.

The mechanism of PEH is unclear. Acute venous distension may account for the acute onset of headache with straining and breath holding. As with primary cough headache, serious underlying conditions must be excluded. Pain from angina may be referred to the head, probably by central connections of vagal afferents, and may present as exertional headache (cardiac cephalgia) upon exercising. Other potential causes include pheochromocytoma, intracranial lesions, and carotid artery stenosis.

Treatment for benign PEH includes indomethacin (25-150 mg/d) and modification of one's exercise regimen. Propranolol may also provide prophylactic benefit. Indomethacin (50 mg), frovatriptan (2.5 mg), ergotamine (1 mg orally), or dihydroergotamine (2 mg intranasally) taken 30 to 45 minutes before exercise can be helpful as prophylaxis.

Primary Headache Associated With Sexual Activity

The pain of primary sex headache usually begins as a dull, bilateral headache that suddenly becomes intense at orgasm. The headache can be prevented or eased by ceasing sexual activity before orgasm. Two types of sex headache are reported: a dull ache in the head and neck that intensifies as sexual excitement increases and a sudden, severe, explosive headache occurring at orgasm. A postural headache developing after coitus can be a presentation of low CSF pressure. Headaches developing at the time of orgasm are not always benign; 5% to 12% of cases of subarachnoid hemorrhage are precipitated by sexual intercourse. Sex headache is reported by men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then disappear, even without an obvious change in sexual activity. In patients who stop sexual activity when headache is first noticed, the pain may subside within a period of 5 minutes to 2 hours. In about half of patients, sex headache will self-remit within 6 months. Comorbid migraine is more likely in this population.

Treatment includes reassurance (once serious causes have been excluded) and advising patients to cease sexual activity if a "warning" headache develops. If the headache occurs regularly, propranolol can be used for prevention (40-200 mg/d) or alternatively diltiazem (60 mg three times a day). Frovatriptan (2.5 mg), ergotamine (1 mg), or indomethacin (25-50 mg) taken about 30 to 45 minutes prior to sexual activity can also be helpful.

Cold-Stimulus Headache

Headache may be triggered in isolation, in the absence of other headache disorders, by external application, or ingestion of a cold stimulus. External cold-stimulus headache is generalized, develops when exposed to cold, and resolves when the stimulus is removed. Ingestion of a cold substance results in a short-lasting frontal or temporal pain. This has been called *ice-cream headache*. Naproxen can be taken premptively to treat cold stimulus headache.

External Pressure Headache

Headache can arise from compression or traction of pericranial structures, for example, as can be experienced with a long ponytail. It is relieved by eliminating the traction or compression.

Primary Stabbing Headache

Primary stabbing headache is characterized by stab-like pains in the head or, rarely, the face, lasting from one to many seconds or minutes and occurring as a single stab or a series of stabs, absence of associated cranial autonomic features, absence of cutaneous triggering of attacks, and a pattern of recurrence at irregular intervals (hours to days). The pains have been variously described as *ice pick pains* or *jabs and jolts* and are more common in patients with other primary headaches, such as migraine and the TACs. If pain is frequent, indomethacin (25-50 mg two or three times a day) can be used for prevention. It is considered in the literature that the perceived trajectory of the stabs may differentiate another syndrome, epicrania fugax; this has no apparent treatment implication.

Nummular Headache

The pain in nummular headache is localized to a round or elliptical focus that is fixed in place, ranging in size from 1 to 6 cm and may be continuous or intermittent. In rare cases, it may be multifocal. Nummular headache is usually continuous with exacerbations, although can be episodic. There may be focal sensory disturbances, such as allodynia or hypesthesia. The pathophysiology is unknown, although a focal neuropathic disorder has been suggested. In the authors' experience, the presentation is best treated by detailing the entire phenotype and treating the underlying primary headache disorder. Local dermatologic or bony lesions must be excluded by examination and investigation. Treatment includes tricyclics, such as amitriptyline, or anticonvulsants, such as topiramate, valproate, or gabapentin. The condition is considered difficult to treat, although this is complex in relationship to any underlying headache disorder.

Hypnic Headache

Hypnic headache is marked by occurrence after a few hours following sleep onset. The headache lasts from 15 to 30 minutes and is typically generalized and moderate in severity, although can also be unilateral and throbbing. Photophobia or phonophobia and nausea are usually absent. Attacks can occur up to three times throughout the night, and daytime naps can also precipitate head pain. Most patients are female, and the onset is usually after age of 60 years. The major secondary consideration in this headache type is poorly controlled hypertension; 24-hour blood pressure monitoring is recommended in such cases.

Patients with hypnic headache usually respond to lithium carbonate (200-600 mg nightly). For those intolerant of lithium, verapamil (160 mg) or indomethacin (25-75 mg) may be tried. One to two cups of coffee or oral caffeine (60-100 mg) at bedtime may be effective in approximately one-third of patients. Case reports suggest that melatonin and flunarizine (5 mg nightly) can also be helpful.

New Daily Persistent Headache

New daily persistent headache (NDPH) is a clinically distinct syndrome, characterized by daily headache from onset for at least 3 months. The patient with NDPH can clearly recall the exact date and moment of onset. The headache usually begins abruptly, although onset may be more gradual in some cases; evolution over 3 days has been proposed as the upper limit for this syndrome. Antecedent illness (such as an upper respiratory infection or viral prodrome) has been reported in about one-third of patients with NDPH in one series. However, often there is no remarkable triggering event. The first priority is to distinguish between a primary and a secondary cause of this syndrome. Subarachnoid hemorrhage is the most serious of the secondary causes and must be excluded either by history or appropriate investigation. Other causes include chronic meningitis as well as abnormalities of CSF pressure (see Chapter 9).

Primary NDPH can be of the migrainous type or can appear featureless, appearing as new-onset TTH. Migrainous features are common and include unilateral headache and throbbing pain; nausea, photophobia, and/or phonophobia occur in about half of patients. Some patients have a previous history of episodic migraine. Treatment of migrainous-type primary NDPH consists of using standard migraine preventive therapies (see earlier discussion). Featureless NDPH tends to be refractory to treatment—although conventional headache preventive therapies (such as tricyclic antidepressants and anticonvulsants) can be offered, most are ineffective.

Posttraumatic Headache

A traumatic event can trigger a headache process that lasts for many months or years after the event. The term *trauma* is used here very broadly: Headache can develop following an injury to the head (including after neurosurgical; dental; or ear, nose, and throat procedures), but it can also develop after an infectious episode such as with viral meningitis or a flu-like illness. The underlying theme appears to be that a traumatic event involving the pain-producing meninges can trigger a headache process that lasts for many years. Complaints of dizziness, vertigo, and impaired memory can accompany the headache. Symptoms may remit after several weeks or persist for months and even years after the injury. Typically, the neurologic examination is normal and computed tomography or MRI studies are unrevealing. However, serious underlying causes must be ruled out, such as chronic subdural hematoma, subarachnoid hemorrhage, and carotid dissection. The headache is best treated by characterizing the phenotype with many patients having migrainous headaches that can be treated with suitable preventives.

57 Facial Pain Disorders and Painful Cranial Neuralgias

Paul G. Mathew and Zahid H. Bajwa

KEY POINTS

1. Facial pain and cranial neuralgias (CN) are poorly understood by clinicians.
2. Facial pain and CN are currently undertreated for a variety of reasons.
3. These chronic pain disorders often lead to and are complicated by anxiety, depression, and insomnia.
4. Evaluation and optimal treatment of sleep disorders and other comorbid conditions is key to optimal therapy.
5. Mechanisms of trigeminal neuralgia and other CN are better defined and understood within the last 20 years.
6. Many behavioral, medical, pharmacologic, nerve blocking techniques, neuromodulation, and surgical interventions are often helpful.
7. Education is needed for all clinicians to understand application of state-of-the-art treatments using interdisciplinary approach.

INTRODUCTION

Painful cranial neuralgias and facial pain disorders are a set of disorders that can occur in isolation or commonly in addition to another headache disorder LEVEL 3.[1] By taking a thorough history and performing a comprehensive physical examination, a clinician can establish the correct diagnosis, which is critical in order to formulate an effective plan of care. Due to overlapping structures and symptoms, the diagnosis and treatment of painful cranial neuralgias and facial pain disorders can truly be a crossroads between neurology, ophthalmology, otolaryngology, and dentistry LEVEL 3.[2,3] Trauma, infections, tumors, and systemic illnesses can all serve as secondary causes for these disorders. As such, when clinical suspicion is elevated, there should be a low threshold for ordering appropriate diagnostic tests and generating referrals to other specialists for further evaluation.

The diagnostic criteria for primary and secondary painful cranial neuralgias and facial pain disorders are detailed in the *International Classification of Headache Disorders* (3rd edition, ICHD-3). ICHD-3 is divided into three parts. Part I focuses on primary headache disorders, covered in Chapter 56. Part II focuses on secondary headache disorders covered in Chapter 56 and in this chapter. Specifically, Part II includes a section on "Headaches or facial pain attributed to disorders of the cranium, neck, eyes, ears, nose sinuses, teeth, mouth or other facial and cervical structures". We cover the disorders that give rise to facial pain in this section. Part III, "Neuropathies and Facial Pains and Other Disorders," is unique in that it includes both primary and secondary disorders that give rise to facial pain, particularly cranial neuralgias and neuropathies. This chapter also includes many of these disorders. Table 57.1 details some of the etiologies of facial pain including primary peripheral nervous system disorders and disorders outside of the nervous system.

FACIAL PAIN DUE TO DISORDERS OF SINUSES, NOSE, AND EARS

Rhinosinusitis

Epidemiology and Pathobiology

Rhinosinusitis by definition is symptomatic inflammation of the nasal cavity (rhinitis) and paranasal sinuses (sinusitis). The terms sinusitis and rhinosinusitis are often used interchangeably because there is nasal cavity involvement in the vast majority of cases LEVEL 3.[4] Rhinosinusitis is extremely common, with adults experiencing one to three episodes per year and an incidence of 15 to 40 episodes per 1,000 patients per year. The inflammation of rhinosinusitis can be associated with genetic factors, environmental influences, occupational factors, infection, allergy, immune dysfunction, and systemic diseases LEVEL 3.[5] Sinus inflammation can activate the nociceptive neurons of the frontal, ethmoid, maxillary, and sphenoid sinuses. The ophthalmic division of the trigeminal nerve innervates the frontal and anterior ethmoid sinuses. The maxillary division of the trigeminal nerve innervates the maxillary, sphenoid, and posterior ethmoid sinuses.

Diagnosis

Rhinosinusitis commonly presents with nasal obstruction/congestion, nasal discharge, postnasal drip, facial pain/pressure, and reduction of smell. Depending on the etiology, other symptoms can also be present. For example, rhinosinusitis secondary to allergies can involve sneezing, watery rhinorrhea, nasal and ocular pruritus, and watery eyes. Likewise, rhinosinusitis secondary to infection can involve fever and purulent discharge.

According to ICHD-3, the diagnostic criteria for headache attributed to rhinosinusitis includes clinical, nasal endoscopic, and/or imaging evidence of current or past infection or other inflammatory process within the paranasal sinuses as well as evidence of causation demonstrated by at least two of the following: (1) Headache has developed in temporal relation to the onset of chronic rhinosinusitis; (2) headache waxes and wanes in parallel with the degree of sinus congestion and other symptoms of the chronic rhinosinusitis; (3) headache is exacerbated by pressure applied over the paranasal sinuses; and (4) in the case of a unilateral rhinosinusitis, headache is localized and ipsilateral to it.

TABLE 57.1 Etiologies of Facial Pain Including Primary Peripheral Nervous System Disorders and Disorders Outside of the Nervous System[a]

Nerve and Sensory Distribution	Primary PNS Disorders	Disorders Outside of the Nervous System	
Trigeminal nerve, ophthalmic division	Classical TN (idiopathic or with vascular loop)	Eyes[b]:	acute angle-closure glaucoma, iritis, uveitis, scleritis, conjunctivitis, trochleitis
	Painful trigeminal neuropathies: • Symptomatic TN (tumor, vascular malformation, multiple sclerosis plaque at dorsal root entry zone) • Herpes zoster ophthalmicus and postherpetic trigeminal neuropathy • Posttraumatic (anesthesia dolorosa)	Sinuses (frontal and anterior ethmoid):	acute rhinosinusitis, septal deflections, hypertrophic turbinates, nasal spurs
		Arteries:	giant cell arteritis (temporal arteritis)
	Paratrigeminal oculosympathetic syndrome (Raeder syndrome)		
Trigeminal nerve, maxillary division	Classical TN	Maxillary teeth:	pulpitis, cracked tooth syndrome, dentine sensitivity, dental abscess
	Painful trigeminal neuropathies: • Symptomatic TN • Acute herpes zoster and postherpetic trigeminal neuropathy • Posttraumatic (anesthesia dolorosa)	Oral cavity:	mucosal malignancies, infections, inflammation, blockage of a major salivary gland duct
		Sinuses (maxillary, sphenoid, posterior ethmoid):	acute rhinosinusitis, chronic rhinosinusitis
Trigeminal nerve, mandibular division	Classical TN	Mandibular teeth, oral cavity, tongue:	as per maxillary teeth and oral cavity
	Painful trigeminal neuropathies: • Symptomatic TN • Acute herpes zoster and postherpetic trigeminal neuropathy • Posttraumatic (anesthesia dolorosa)	Temporomandibular joint:	temporomandibular disorders: arthritic and degenerative joint disease, disk displacement, myalgia, and myofascial pain
	Auriculotemporal syndrome (Frey syndrome)	External auditory meatus, anterior pinna:	laceration and tumors of pinna: external otitis, foreign bodies, squamous cell and basal cell carcinomas, adenocarcinoma
	Burning mouth syndrome		
		Arteries:	giant cell arteritis (temporal arteritis)
Facial nerve, nervus intermedius branch	Nervus intermedius neuralgia	Mastoid cells and skin overlying the mastoid process:	otitis media, mastoiditis
	Trigeminal neuropathies: • Herpes zoster (Ramsey Hunt syndrome) and postherpetic neuralgia	External auditory meatus, lateral pinna:	external otitis, foreign bodies, local tumors
	Acoustic neuroma	Nasopharynx, palate:	local/infiltrative tumors, inflammation
Glossopharyngeal nerve and vagal nerve	Glossovagopharyngeal neuralgia	External ear canal and tympanic membrane:	external otitis, foreign bodies, squamous cell and basal cell carcinomas, adenocarcinoma, tympanic membrane perforation
	Nerve compression by elongated styloid process (Eagle syndrome)	Upper pharynx, posterior tonsils, base of tongue, soft palate:	local tumors, inflammation, infection

Abbreviations: CYP450, cytochromes P450; PNS, peripheral nervous system; TN, trigeminal neuralgia.
[a]Pain in a specific distribution should warrant consideration of the various etiologies listed in addition to consideration of central nervous system causes.
[b]Eye pain without ophthalmoplegia.

Although rhinosinusitis is very common, "sinus headache" as self-diagnosed by patients or diagnosed by physicians is more often due to migraine than actual sinus pathology. The Sinus, Allergy and Migraine Study recruited 100 participants over the age of 18 with self-diagnosed sinus headaches, and 86% of them were found to have migraine or probable migraine LEVEL 3.[6] Migraine and headaches secondary to sinus disease have many similarities, which is the reason for the frequent misdiagnosis. Both of these conditions can occur more frequently with the change of seasons, barometric pressure, and precipitation. The distribution of pain can involve V_1 and V_2 distributions of the trigeminal nerve for both conditions. Migraine can involve autonomic dysfunction including rhinorrhea, nasal congestion, and lacrimation, which can all occur with sinus disease. There is also an element of reinforcing behavior. Many patients will think they have a sinus infection causing their headaches, take a course of antibiotics, and experience a resolution of their headache. These patients assume that eradication of an infection lead

to the resolution of their headache, when in fact, the headache was due to migraine, which would have resolved with time regardless of intervention. To differentiate between these two conditions, sinus headaches do not typically involve migrainous features, such as throbbing/disabling pain, photophobia, phonophobia, and nausea. On the other hand, migraines do not typically involve fever or purulent nasal discharge. Another feature that can be used to different these two conditions is response to triptans because a triptan should be effective for the treatment of migraine but not sinus headache LEVEL 3.[2]

If sinus disease is suspected as the cause of headache, computed tomography (CT), magnetic resonance imaging (MRI), or endoscopic evaluation should be considered. It should be reinforced to patients that nonacute sinus mucosal changes are common in the general population and should not be considered an indication that a headache is secondary to sinus disease.

Management and Outcome

Rhinosinusitis depending on the etiology can resolve spontaneously. Over-the-counter therapies such as acetaminophen, ibuprofen, decongestants, and saline irrigation can be useful. Antibiotics should be considered if there is high clinical suspicion for bacterial infections. Symptoms suggestive of a bacterial infection include pain in the cheeks/teeth, a high fever that does not subside, purulent discharge, and lack of response to decongestants. In addition, intranasal glucocorticoids can be useful for the treatment of viral and bacterial rhinosinusitis. A Cochrane systematic review of using intranasal glucocorticoids for the treatment of rhinosinusitis demonstrated a moderate-sized benefit for the treatment of nasal blockage and a small benefit for the treatment of rhinorrhea. The use of intranasal glucocorticoids is not without risk because the chances of developing epistaxis is increased LEVEL 3.[7] Failure to adequately treat infectious rhinosinusitis can result in brain abscess, subdural empyema, meningitis, cavernous sinus thrombosis, epidural abscess, and osteomyelitis LEVEL 3.[8]

Facial Pain Attributed to Disorders of Intranasal Mucosal Contact Points

Epidemiology and Pathobiology

Intranasal mucosal contact points have been cited both in the neurology and otolaryngology literature as potential causes of facial pain. Contact points can occur between septal spurs, hypertrophic turbinates, and surrounding segments of mucosa. It is speculated that the intranasal contact point causes an irritation to the trigeminal system, which presents as retronasal, glabellar, or ipsilateral cheek pressure/pain. The prevalence of intranasal mucosal contact points varies tremendously between different studies. In one study involving 973 patients with a provisional diagnosis of rhinosinusitis, 4% of the patients had an intranasal contact point, and 42% of the patients had facial pain associated with their rhinosinusitis. There was no clear association between the presence of an intranasal contact point and facial pain. In another study involving 100 patients, 55% had intranasal contact points and 29% suffered from headaches, but the presence of a contact point was inversely related to the presence of pain. In a systemic review involving these and several other studies, it was found that the majority of patients with intranasal contact points did not have significant facial pain LEVEL 3.[9]

Diagnosis

Intranasal contact point–induced headache/facial pain is not listed as a specific diagnosis in ICHD-3 but more broadly fits under the category of "Headache and/or facial pain caused by a disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cervical structure." The diagnostic criteria for this broad category includes headache and/or facial pain has developed in temporal relation to the onset of the disorder or appearance of the lesion, headache and/or facial pain is localized in accordance with the site of the lesion, headache and/or facial pain is exacerbated by pressure applied to the lesion as well as either or both of the following: (1) Headache and/or facial pain has significantly worsened in parallel with progression of the disorder or lesion and/or (2) headache and/or facial pain has significantly improved or resolved in parallel with improvement in or resolution of the disorder or lesion. In addition to these criteria, other diagnostic criteria include visualizing the contact point on CT, MRI, and/or endoscopy as well as improvement/resolution of pain with local anesthetic application to the contact point LEVEL 3.[10]

Management and Outcome

In general, intranasal contact points are often incidental findings and not predictive of headache or facial pain. In addition, surgical decompression of intranasal contact points in patients with headache/facial pain does not consistently result in a total elimination of pain. Surgical decompression should be considered when the headache and/or facial pain is ipsilateral to the side of the contact point. Although response to intranasal anesthetics can be a useful part of the evaluation, some patients with severe abutting of structures may not experience significant relief. In cases where there is a partial response to decompression, it is possible that the intranasal contact point may actually be serving as a trigger for a coexisting primary headache disorder such as migraine LEVEL 3.[11]

Surgical decompression of an intranasal contact point often involves both a septoplasty and turbinate reduction. In such cases, there can be significant improvement in the patency of the nose, which can lead to an improvement of sleep quality. In patients with sleep apnea/hypopnea, surgical reductions in airway resistance can lead to a reduction in required positive airway pressure, which can lead to better tolerability/compliance. Sleep dysfunction is a well-known trigger for numerous headache and facial pain disorders LEVEL 3.[12] As such, the potential improvement of sleep with intranasal contact point decompression may be another mechanism for the improvement of headache/facial pain.

Otalgia Attributed to Disorder of Ears and Referred Pain

Epidemiology and Pathobiology

The sensory innervation of the ear is highly complex (Fig. 57.1). Sensation is mediated by the auriculotemporal nerve/CN V (lateral surface of the tympanic membrane, external acoustic meatus, temporal scalp, preauricular area, tragus, temporomandibular joint), nervus intermedius/CN VII (lateral surface of the tympanic membrane, external acoustic meatus, concha), a branch of the glossopharyngeal nerve/CN IX (middle ear, medial surface of the tympanic membrane, mastoid air cells), a branch of the vagus nerve/CN X (lateral surface of the tympanic

FIGURE 57.1 Sensory innervation of the ear. (From DeLange JM, Garza I, Robertson CE. Clinical reasoning: a 50-year-old woman with deep stabbing ear pain. *Neurology*. 2014;83[16]:e152-e157.)

membrane, external acoustic meatus, concha), and the lesser occipital nerve/C2-C3 (posterolateral scalp, superior pinna, supra-auricular scalp) LEVEL 3.[13] Nearly half of all cases of otalgia or ear pain are due to structural pathology of the external or middle ear, with the remainder of cases occurring as a result referred pain from remote structures LEVEL 3.[14]

Acute otitis media is a common primary ear disorder that can cause otalgia. In terms of global incidence, children younger than age 5 years have an incidence of 45 to 60 new episodes per 100 people per year, children 5 to 14 years of age have 19 to 22 new episodes per 100 people per year, patients 15 to 24 years of age have 3.1 to 3.5 new episodes per 100 people per year, and adults 25 to 85 years of age have 1.5 to 2.3 new episodes per 100 people per year LEVEL 3.[15]

Diagnosis

Depending on the etiology, pain can be accompanied by fullness, tenderness, burning, or itching. Routine otoscopy can be useful, but further evaluation with MRI or an otolaryngology referral should be considered based on clinical suspicion. In addition to otitis media, other diagnostic considerations should include external otitis; foreign bodies; as well as squamous cell, basal cell, and adenocarcinoma.

FACIAL PAIN DUE TO TEMPOROMANDIBULAR DISORDERS AND DISORDERS OF THE TEETH OR MOUTH

Pain within the oral cavity can have a wide differential diagnosis. If the pain involves a specific tooth or set of teeth, pulpitis, dentine sensitivity, dental abscess, and cracked tooth syndrome should all be considered. Other sources of oral cavity pain include mucosal malignancies, infections, inflammation, and blockage of a major salivary gland duct.

Temporomandibular Disorders

Epidemiology and Pathobiology

Temporomandibular disorder (TMD) is a term that is used to encompass disorders of the temporomandibular joint and/or associated structures. It is estimated that approximately 10% of adults older than the age of 18 experience TMD pain. It tends to involve young and middle age adults rather than pediatric and elderly populations. In addition, women are twice as likely to suffer from TMD LEVEL 3.[16] TMD tends to occur frequently in patients with primary headache disorders including migraine and tension-type headache. In the presence of a single TMD symptom, there tends to be associated headache in approximately 56.5% of cases LEVEL 3.[17]

The temporomandibular joint is a very complex joint, which receives its sensory innervation from the mandibular branch of the trigeminal nerve (Fig. 57.2). A cartilaginous disc facilitates the rotational and translational movements between the mandibular condyle and the temporal bone. TMD can be broken down into muscle disorders, disc displacements, arthralgia, osteoarthritis, and osteoarthrosis. Muscle overactivity in the form of clenching and bruxism can have deleterious effects on the joints and teeth. In addition to destruction of enamel, there can also be migration of the teeth within the gums, leading to gap formation and alteration of occlusion.

Clinical Manifestations and Diagnosis

The temporomandibular joint facilitates talking, chewing, and facial expressions. Jaw pain associated with TMD can result in restrictions of all of these activities. The quality of the pain can be variably described as throbbing, aching, or sharp with radiation to the masseters along the angle of the mandible, the temples, and the ear.

Due to pain and tightness of the joint, there can often be limited mouth open, which becomes particularly prominent in cases involving disc displacement. In severe cases, TMD can cause reductions in dietary intake, resulting in malnutrition and

FIGURE 57.2 The temporomandibular joint. (From DeLange JM, Garza I, Robertson CE. Clinical reasoning: a 50-year-old woman with deep stabbing ear pain. *Neurology*. 2014;83[16]:e152-e157.)

pathologic weight loss. In addition to pain, audible popping/clicking can occur, which can be very bothersome to both the patient and others in close proximity. Chronic TMD can lead to compensatory postural changes, which can result in the development of chronic neck pain. The symptoms and referral patterns of TMD can be both unilateral or bilateral.

X-ray and CT imaging can be useful for confirming suspected bony changes to the anatomy including dislocation and degenerative changes to the joint. MRI tends to be more effective in demonstrating pathology of the cartilaginous disc and other soft tissue anatomy.

Treatment and Outcome

TMD symptoms can wax and wane over time. As such, symptomatic flares often resolve spontaneously without any intervention. Patients often reactively will avoid certain foods and limit jaw use, which can at times hasten the resolution of symptoms. Physical therapy, biofeedback, and oral appliances can be useful in cases with persistent symptoms. Oral appliances, which in some cases are worn continuously except during meals, can be an effective treatment for TMD by stabilizing potential occlusion issues and relaxing overactive muscles. Although over-the-counter appliances are available, they may not be the best choice. Over-the-counter appliances tend to be bulkier and less comfortable, which can lead to noncompliance and/or involuntary expulsion during sleep. Also, due to the noncustom nature of over-the-counter appliances, use can lead to worsening of a malocclusion and exacerbation of TMD.

Pharmacologic agents commonly used for the treatment of TMD include nonsteroidal anti-inflammatory drugs, muscle relaxants, corticosteroids, tricyclic antidepressants, anticonvulsants, and benzodiazepines LEVEL 1,[18] botulinum toxin (BTX) injections into the temporalis, masseters, and/or other muscles of mastication can also be an effective treatment. It is unclear whether the positive effect of BTX is due to muscle relaxation, a downregulation of sensory nerve transmission, or a combination of these factors LEVEL 1.[19] In clinic-based samples, TMD commonly occurs with migraine and can be an exacerbating factor.

CRANIAL NEURALGIAS

Trigeminal Neuralgia

Epidemiology and Pathobiology

Trigeminal neuralgia (TN) is a disabling condition that involves lancinating paroxysms of facial pain that is usually unilateral. The annual incidence of TN is 4 to 13 per 100,000 people. The incidence increases with age, and most idiopathic cases occur to those older than the age of 50 years. There is a male to female ratio of about 1:1.7 LEVEL 1.[20,21]

TN occurs when there is compression or irritation of the trigeminal nerve. Lesions that are more proximal will involve more divisions of the nerve. The term *classical* TN refers to TN that is caused by compression of the nerve by a blood vessel near the root entry zone of the pons. The blood vessel most commonly implicated in cases of vascular compression is the posterior inferior cerebellar artery.

It is thought that over time, chronic compression causes focal demyelination and aberrant sensory impulses. This is likely why age and hypertension are risk factors for the development of TN. There are some estimates that as many as 91% of TN cases are due to vascular compression LEVEL 1.[22]

In addition to vascular compression, acute herpes zoster/postherpetic neuralgia, trauma, multiple sclerosis, vestibular schwannomas/acoustic neuromas, cerebellopontine meningiomas, cysts including epidermoid cysts, saccular aneurysms, and arteriovenous malformations have all been associated with secondary TN LEVEL 1.[23]

Clinical Manifestations and Diagnosis

According to ICHD-3 criteria, the pain occurs in one or more divisions of the trigeminal nerve, with no radiation beyond the trigeminal distribution, and must involve at least three of the following four characteristics: (1) recurring in paroxysmal attacks lasting from a fraction of a second to 2 minutes; (2) severe intensity; (3) electric shock-like, shooting, stabbing, or sharp in quality; and/or (4) at least three attacks precipitated by innocuous stimuli to the affected side of the face.

In terms of distribution, TN usually involves the second and/or third divisions of the trigeminal nerve with first division involvement occurring in <5% of patients. Although individual attacks are short in duration, there can be many attacks per day, but between attacks, there are often interictal periods during which, trigger zones become inactive. Patients are usually pain free during these refractory periods, but a dull background pain may persist in some long-standing cases. Attack periods can last for weeks to months, which can be followed by remissions that can last months or even years, but the pain usually returns.

Attacks can be triggered by trivial stimuli including washing, shaving, smoking, eating, talking, and/or brushing the teeth but often occur spontaneously. By definition, at least three attacks should be triggered by contact in order to meet the diagnostic criteria for TN. Less frequently, attacks can be triggered by somatosensory stimuli outside the trigeminal area, such as a limb, or by other sensory stimulation such as bright lights, loud noises, or tastes. In some cases, TN pain can trigger ipsilateral facial spasm, which is why TN is at times referred to as *tic douloureux*.

TN does not typically involve ipsilateral autonomic features that can be seen with short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) or short-lasting unilateral neuralgiform headache with autonomic symptoms (SUNA). As such, if a patient presents with conjunctival injection, lacrimation, nasal congestion, rhinorrhea, ptosis, miosis, and/or forehead/facial sweating ipsilateral to the side of facial pain, SUNCT and SUNA should be considered in the differential diagnosis. In clinical practice, patients often not only deny the presence of these features during an attack but also do not typically look in the mirror during an attack. As such, asking the patient to take photographs during an attack or having a friend/family member observe the patient during an attack are reasonable maneuvers that can be helpful to confirm the diagnosis.

Although vascular compression is the most common structural cause of TN, up to 15% of patients can have other structural causes. Features that increase risk of an underlying lesion include trigeminal sensory deficits, bilateral involvement of the trigeminal nerve, and younger age LEVEL 3.[24] Bilateral TN is extremely rare, but multiple sclerosis is an etiology that has been commonly implicated. Acute herpes zoster/postherpetic neuralgia most commonly affects the ophthalmic division of the trigeminal nerve.

MRI with contrast and fine cuts throughout the course of the trigeminal nerve can be very useful in order to confirm compression, determine surgical candidacy, and confirm that there is no other secondary cause for TN pain. Axial fast imaging employing steady-state acquisition and three-dimensional–spoiled gradient echo are multiplanar reconstruction sequences can be particularly useful.

Treatment and Outcome

The goal of TN treatment is to reduce the frequency and intensity of attacks. First-line treatment is with oral medications. With all therapies, it is recommended to start at a low dose, and titrate slowly until pain is in remission unless the patient experiences intolerable side effects. In refractory cases, it is not unusual for patients to be on multiple medications. Carbamazepine has level A evidence supporting its use in TN. Titrations can start at 100 mg daily and reach a dose of 600 mg twice a day. Prior to starting carbamazepine, testing for the HLA-B*1502 allele should be considered in patients of Asian ancestry because they are at high risk for Stevens-Johnson syndrome and toxic epidermal necrolysis. Some other medications that are probably effective include oxcarbazepine (level B, titration: 300 mg daily → 900 mg twice a day), baclofen (level C, titration: 5 mg every 8 h → 80 mg/d), lamotrigine (level C, titration: 50 mg daily → 400 mg daily). Phenytoin, valproic acid, gabapentin, pregabalin, and topiramate have small studies supporting their effectiveness in the treatment of TN LEVEL 2.[24] In the emergency department or urgent care settings, intravenous phenytoin, valproic acid, and levetiracetam can be a useful options LEVEL 3.[25-27] For TN cases that do not respond adequately to oral treatment, there is some evidence to suggest that onabotulinum toxin type A (BTX) treatment can be a relatively safe treatment option. When performing BTX injections for the treatment of TN, injections should be performed symmetrically regardless of the distribution of pain given the facial asymmetry that can result from unilateral facial weakness LEVEL 3.[28] Table 57.2 details medications, which are commonly used in the treatment of cranial neuralgias.

For refractory cases of TN, more invasive options could be considered. These options are divided into trigeminal nerve–sparing procedures and denervating/destructive procedures. In terms of nerve-sparing procedures, microvascular decompression is a procedure that can at times be curative. This procedure involves performing a craniotomy (approximately 2 in) to exposes area posterior to ear. Under microscope, blood vessels (usually the superior cerebellar artery, posterior inferior cerebellar artery) and any other adjustment abutting structures are decompressed from nerve, and Teflon felt is placed in between the structures. Microvascular decompression tends to generate faster improvement of pain and has longer lasting benefit than some of the nerve destructive procedures LEVEL 1.[29] As with any neurosurgical procedure, risks include meningitis, encephalitis, intracranial hemorrhage, stroke, cranial nerve deficits, neuralgias, and cerebral spinal fluid (CSF) leak.

In terms of denervating/destructive procedures, peripheral trigeminal neurectomies were among the first procedures that were performed. These procedures caused dense numbness, tended to have early recurrence of pain, and only treated small areas innervated by superficial branches of the trigeminal nerve. Over time, techniques targeting proximal targets were devised, and rhizotomies have replaced neurectomies. Targeting the root exit zone rather than superficial branches tends to treat larger areas of pain, have longer lasting results, and have fewer side effects. Rhizotomies are particularly useful in patients who have contraindications to microvascular decompression or have experienced inadequate relief.

Rhizotomies are performed via percutaneous needle insertion to the root exit zone of the trigeminal nerve under fluoroscopy (Fig. 57.3). Once the root exit zone is reached, mechanical disruption with balloon compression, chemical disruption with glycerol, or radiofrequency ablation can be performed. Balloon compression and glycerol rhizotomies are nonselective techniques, which means there is no way during the procedure to confirm that the desired nerve distribution is being treated and that nondesired nerve distributions are not being treated. In addition, with these techniques, other than visualization with fluoroscopy and CSF return from the needle, there is no other confirmation that the needle is in adequate proximity of the root exit zone for the procedure to have any effect. In review of multiple studies comparing rhizotomy techniques, it was found that balloon compression was more likely to affect mastication, and glycerol rhizotomies had the highest recurrence rates. Adverse

TABLE 57.2 Medications Commonly Used in Cranial Neuralgias

Medication	Maintenance Dose	Side Effects	Additional Considerations
Carbamazepine	300-1,200 mg/d	Sedation, dizziness, cognitive impairment, hyponatremia, rash, aplastic anemia	• Multiple drug interactions (CYP450 inducer) • Response can be seen within 48 h.
Oxcarbazepine	600-1,800 mg/d	Less severe than with carbamazepine but include sedation, dizziness, hyponatremia, rash	• Cross-allergy with carbamazepine in 25% of cases • Equally effective to carbamazepine
Gabapentin	600-2,400 mg/d	Sedation, peripheral edema	• Extra doses can be used for acute treatment.
Lamotrigine	150-400 mg/d	Stevens-Johnson syndrome, sedation, dizziness	• Very slow dose up titration necessary
Baclofen	30-80 mg/d	Sedation, ataxia, fatigue	• Risk of seizures if stopped rapidly
Phenytoin	200-400 mg/d	Sedation, ataxia, cognitive impairment, rash	• Multiple drug interactions (CYP450 inducer) • Used as an initial intravenous treatment but therapeutic effect lost quickly
Tizanidine	12 mg/d	Sedation, dizziness, orthostatic hypotension	• Therapeutic effects are lost within 1-3 mo.
Levetiracetam	3-4 g/d	Irritability, depression	• Used as an add-on therapy
Onabotulinum toxin A	75 units	Facial weakness, transient edema	• 5 units (0.1 mL) injected in 15 points in epidermis/dermis or submucosally to region affected

Abbreviation: CYP450, cytochromes P450.
[a]Evidence for use derived from trigeminal neuralgia clinical studies.

effects of denervating/destructive procedures include sensory loss, dysesthesias, and anesthesia dolorosa (painful numbness). In contrast, radiofrequency ablation is the only selective technique because stimulation is performed prior to ablation to ensure the correct target. This is of particular importance as unintended treatment or overtreatment of the ophthalmic branch of the trigeminal nerve can lead to reduction of corneal sensation, which can lead to exposure keratopathy and, in severe cases, permanent vision loss LEVEL 3.[30,31]

FIGURE 57.3 Rhizotomies are performed via percutaneous needle insertion to the root exit zone of the trigeminal nerve under fluoroscopy.

Among rhizotomy techniques, radiofrequency ablation tends to have the highest rates of initial pain relief and the lowest rates of pain recurrence. With balloon compression, pain control rates up to 91% at 6 months and 66% at 3 years have been reported. With glycerol rhizotomy, pain control rates up to 90% at 6 months and 54% at 3 years have been reported. With radiofrequency thermocoagulation, pain control rates up to 97% initially and 58% at 5 years have been reported. Some advantages of rhizotomies include shorter procedure duration, minimal anesthesia risk, and in the case of glycerol rhizotomy and radiofrequency thermocoagulation, immediate patient feedback LEVEL 3.[32]

Stereotactic radiosurgery (Gamma Knife, CyberKnife) is another denervating/destructive procedure that can be employed for the treatment of TN (Fig. 57.4). Stereotactic radiosurgery involves the use of highly focused beams of ionizing radiation

FIGURE 57.4 Schematic of Cyber Knife/Gamma Knife treatment.

that converge on a small target zone with high precision. This technique can be effective for the treatment of small tumors, vascular lesions, and functional disorders like TN. It is particularly useful for targets that are inaccessible for open surgery but not ideal for use with large targets. With stereotactic radiosurgery, pain relief can occur anywhere from 48 hours to 30 days post-procedure, pain recurrence can happen in over 30% of patients, and over 14% can experience hypoesthesia LEVEL 3.[33]

In clinical practice, isolated neuralgias can at times present in distal branches of the trigeminal nerve including the supraorbital, supratrochlear, and auriculotemporal nerves. Nerve blocks can provide transiently relief of pain after the injection in nearly all cases, but some patients will have lasting pain relief for weeks, months, or even years after the procedure (Fig. 57.5). The mechanism behind this lasting benefit is unclear, but one hypothesis is that injections using higher volumes of solution are expanding otherwise tight planes of fascia and muscle that are causing compression the nerves. If this technique provides inadequate relief of a trigeminal nerve branch focal neuralgia, surgical decompression could be considered LEVEL 3.[34,35]

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia (GN) is a disorder that involves pain in the posterior part of the tongue, tonsillar fossa, pharynx, beneath the angle of the lower jaw, and/or in the ear. According to ICHD-3 criteria, the pain must have at least three of the following four characteristics: (1) recurring in paroxysmal attacks lasting from a few seconds to 2 minutes; (2) severe intensity; (3) shooting, stabbing, or sharp in quality; and (4) precipitated by swallowing, coughing, talking, or yawning. Annual incidence rates for the disorder is 0.7 per 100,000 person-years. Overall, age-specific crude rates increased slightly with age. Bilateral presentations can occur in 25% of patients, and patients need surgical intervention for adequate relief of symptoms in 25% of cases LEVEL 3.[36]

The nerve distribution of GN includes sensory branches from the auricular and pharyngeal branches of the glossopharyngeal nerve as well as the vagus nerve. As such, the previously used term for this disorder is *glossovagopharyngeal neuralgia*, and some cases involve vagal symptoms including cough, hoarseness, syncope, and/or bradycardia. Due to these symptoms, patients can experience significant unintended weight loss due to reduced oral intake. GN can be episodic with weeks to months of being symptom free before the pain returns. GN tends to be responsive to anticonvulsants. In some cases, application of local anesthetic to the tonsil and pharyngeal wall can transiently prevent attacks. Like TN, imaging studies can demonstrate neurovascular compression, and microvascular decompression of the glossopharyngeal nerve and possibly the vagus nerve can lead to an improvement/resolution of symptoms. Adverse events associated with surgery include meningitis, encephalitis, intracranial hemorrhage, stroke, CSF leaks, unilateral hearing loss, imbalance, and difficulty swallowing. Rhizotomy and stereotactic radiosurgery are also therapeutic options for the treatment of refractory GN.

Nervus Intermedius Neuralgia

Nervus intermedius neuralgia (NIN) is a disorder that involves lancinating pain deep in the auditory canal, which can radiate to the parieto-occipital region. According to ICHD-3 criteria, the pain must have at least three of the following four characteristics: (1) recurring in paroxysmal attacks lasting from a few seconds to minutes; (2) severe intensity; (3) shooting, stabbing, or sharp in quality; and (4) precipitated by stimulation of a trigger area in the posterior wall of the auditory canal and/or periauricular region.

The other name for this disorder is facial nerve neuralgia because the nervus intermedius is a branch of CN VII, which innervates external auditory canal, middle ear, nasopharynx, and palate. Some cases of NIN can involve lacrimation, salivation, and/or taste alteration.

As part of the evaluation for NIN, MRI of the brain should be performed to look for secondary causes of ear pain. Visualization of nervus intermedius on MRI is challenging because it is much smaller than the trigeminal and glossopharyngeal nerves. When considering causes for ear pain, nervus intermedius neuropathy attributed to herpes zoster, also known as *Ramsay Hunt syndrome*, should be considered. As with any case of shingles, vesicular eruptions can occur in the ear and/or oral mucosa. Some cases can involve peripheral facial paresis. NIN tends to be responsive to anticonvulsants. Like TN, interventional/surgical techniques can be used for treatment of refractory cases of NIN.

FIGURE 57.5 Nerve block sites for the trigeminal nerve.

Occipital Neuralgia

Epidemiology and Pathobiology

Occipital neuralgia (ON) is a disorder that involves pain in the distribution of the greater, lesser, and/or third occipital nerves. The pain can be unilateral or bilateral and can involve ipsilateral neck pain. There are limited data regarding the prevalence of ON, but it is highly underdiagnosed in clinical practice. In one study evaluating the prevalence of ON in a community hospital-based headache clinic, it was found that about 25% of patients presenting with a chief complaint of headache had ON. Among the patients with ON, only 15% presented with ON as the chief complaint without another headache disorder, whereas 85% of ON cases occurred in patients having a chief complaint of another headache disorder, which most commonly was common migraine. If undiagnosed, inadequate treatment of ON can trigger an increase in the frequency and intensity of other comorbid headache disorders and sleep dysfunction LEVEL 3.[37]

Clinical Manifestations and Diagnosis

According to ICHD-3 criteria, the pain must have at least two of the following three characteristics: (1) recurring in paroxysmal attacks lasting from a few seconds to minutes; (2) severe intensity; and (3) shooting, stabbing, or sharp in quality. The criteria also include that ON must involve dysesthesia and/or allodynia apparent during innocuous stimulation of the scalp and/or hair and one or both of the following: (1) tenderness over the affected nerve branches or (2) trigger points at the emergence of the greater occipital nerve or in the area of distribution of C2. A therapeutic response occipital nerve blocks is part of the diagnostic criteria for ON.

On physical examination, occipital Tinel's testing, which involves the examiner tapping his or her fingers along the skull base, can trigger lancinating pain/paresthesias confined to the corresponding nerve distribution. A positive Tinel sign is present in about 75% of patients with ON. In addition, neck passive range of motion can elicit similar lancinating pain/paresthesias.

Treatment and Outcome

Occipital nerve blocks are not only part of the diagnostic criteria for ON but also can be therapeutic. Nerve blocks are performed with an anesthetic (usually lidocaine, bupivacaine, or a combination) with or without a steroid. Methylprednisolone and triamcinolone are two of the more commonly used steroids. There are some data to support the use of steroid alone, but lack of immediate relief may reduce patient satisfaction.

Occipital nerve blocks are generally safe, well-tolerated office-based procedures, which can have prolonged effects beyond the duration of the injected anesthetic (Fig. 57.6). Factors that can influence variability of response include medications injected, technique, and volume of solution. In one retrospective chart review study involving 41 subjects with ON, large-volume nerve blocks (6 mL per side) were used to confirm the diagnosis. Among the patients, the average duration of ON complete remission was 206.95 days with a range of 4 to 840 days. This duration of benefit is an underestimate because pain may not have returned at the time of their follow-up visit, and it is unknown if and when their lancinating ON pain returned, which would make the actual duration of benefit unknown.

No long-term side effects were noted after any of the nerve blocks performed. A possible mechanism of action is that the hydrodynamic pressure generated by injecting the solution is causing an expansion of tissue planes. This tissue plane expansion may result in nerve decompression, which may correlate with long duration of benefit and even complete resolution of pain in certain patients LEVEL 3.[38] If nerve blocks do not provide adequate relief, preventative treatment with tricyclic antidepressants or anticonvulsants could be considered. In refractory cases, occipital nerve decompression surgery could be considered LEVEL 3.[39]

FIGURE 57.6 Occipital nerve block site.

IDIOPATHIC FACIAL PAIN

Burning Mouth Syndrome

Burning mouth syndrome (BMS) is a condition that involves intraoral burning or a dysesthesic sensation without any clear cause that occurs daily for more than 2 h/d for more than 3 months. When confined to the tongue, the names stomatodynia and glossodynia have been used to label this condition.

BMS most commonly affects peri- and postmenopausal females. BMS has an association with anxiety and depression, and psychosocial issues can trigger/exacerbate BMS. The underlying cause of BMS has not been fully elucidated. One possible mechanism is that there is a loss of epithelial and subpapillary small nerve fibers of the tongue. It has also been demonstrated that BMS can involve upregulation of the TRPV1 heat and capsaicin-activated cation channels.

According to ICHD-3 criteria, the pain must have a burning quality and must be felt superficially in the oral mucosa. On examination, the oral mucosa should have a normal appearance and sensory evaluation should be normal. It is important to rule out intraoral secondary causes of BMS including candidiasis, lichen planus, and hyposalivation as well as systemic secondary causes including medication side effect, anemia, vitamin B_{12} deficiency, folic acid deficiency, Sjögren syndrome, and diabetes. BMS is often bilateral, and the most commonly affected area is the tip of the tongue.

Although some cases can have a constant daily pattern, the intensity tends to fluctuate. Some patients may also experience perceived dry mouth and alteration of gustation. Dysgeusia may be due to denervation of the chorda tympani fibers that innervate the fungiform buds of the tongue.

Tricyclic antidepressants, selective serotonin reuptake inhibitors, serotonin norepinephrine reuptake inhibitors, and hormone replacement therapy have all demonstrated some efficacy. Topical treatments including clonazepam and capsaicin can also be useful. In refractory cases, polypharmacy, cognitive behavioral therapy, and transcranial magnetic stimulation are used LEVEL 3.[40,41]

Persistent Idiopathic Facial Pain

Persistent idiopathic facial pain (PIFP), which was previously known as atypical facial pain, is a facial and/or oral pain that occurs on a daily basis for at least 2 h/d for at least 3 months based on ICHD-3 criteria. By definition, PIFP has a dull, aching, or nagging quality and is poorly localized without following the distribution of a peripheral nerve. Part of the criteria specifies that dental causes must be excluded and a neurologic examination must be normal.

The lifetime prevalence of PIFP is estimated to be 0.03% (1 of 3,336) LEVEL 3.[42] PIFP tends to occur more often in women and frequently occurs in the setting of other chronic pain disorders, psychiatric diagnoses, and irritable bowel syndrome. PIFP can feel superficial or deep and can involve superimposed sharp pain. Stress can be a trigger of the pain, and over time, the pain can migrate to areas outside of the trigeminal distribution. PIFP can at times start after trauma or a procedure involving the face and/or oral cavity. Like many forms of neuropathic pain, even after tissue healing has occurred, pain can persist. If there is only pain of one or more teeth or after extraction without an identifiable cause of pain, the term *atypical odontalgia* has been used. If the insult is more significant and there are sensory deficits, the diagnosis of painful posttraumatic trigeminal neuropathy should be considered LEVEL 3.[23]

Pharmacologic treatment options include amitriptyline, gabapentin, topiramate, venlafaxine, and fluoxetine LEVEL 3.[43] For the treatment of refractory cases, pulsed radiofrequency ablation of the sphenopalatine ganglion, peripheral nerve field stimulation, and BTX injections can be considered LEVEL 3.[44]

Primary Headache Disorders Presenting as Facial Pain

The vast majority of primary headache disorders involve facial pain if facial pain is defined as involvement of one or more branches of the trigeminal nerve. In other words, it would be exceedingly unusual for a case of migraine, tension-type headache, or cluster headache to have no involvement of the forehead, orbits, or temples. On the other hand, if facial pain is defined as pain in the lower half of the face (V_2, V_3 excluding the temples), facial pain as a manifestation of a primary headache disorder becomes much less common. In the case of migraine, these cases are referred to as *facial migraine* or *lower half headache*. Facial pain can accompany the typical cranial distribution of migraine pain in 8.9% of patients with migraine, whereas isolated lower facial pain without the typical cranial distribution of migraine pain occurs in about 0.2% of patients with migraine. In addition, patients with a facial pain component to their migraines tend to experience more autonomic features with their attacks (47%) than patients with migraine without facial pain with autonomic features (7.9%) LEVEL 3.[44] The presence of migrainous features including photophobia, phonophobia, nausea, vomiting, and aura should prompt consideration of the possible diagnosis of a migraine variant with facial pain involvement. This should then prompt trials of migraine preventative and abortive agents, including triptans. An improvement of facial pain after triptan administration can further substantiate this diagnosis. Other primary headache disorders, including cluster headache and paroxysmal hemicrania, can present with lower half of facial pain.

Complex Regional Pain Syndrome 58

Steven P. Cohen, Michael L. Weinberger, and Thomas H. Brannagan III

KEY POINTS

1. Complex regional pain syndrome type 1 is characterized by pain that is disproportionate to the degree of injury and has now been designated to be nociplastic pain.
2. Complex regional pain syndrome type 2 is a pain syndrome following nerve injury.
3. Physical therapy and functional restoration programs form the cornerstone of treatment for complex regional pain syndrome.

INTRODUCTION

Complex regional pain syndrome (CRPS) has a long and changing history in medical practice. Veldman suggested that Ambrose Pare, in 1598, may have been the first to describe the syndrome of widespread limb pain accompanied by swelling, discoloration, and temperature change. Silas Weir Mitchell, a civil war era physician, discussed the relationship of central and peripheral mechanisms and "reflex transfers" in the spinal cord along with his description of soldiers who experienced intense nerve pain and autonomic dysregulation after gunshot wounds sustained in battle. The term *causalgia* is attributed to Mitchell, whereas the term *reflex sympathetic dystrophy* (RSD) was coined by Evans 80 years later. Other terms used to describe the constellation of signs and symptoms now known as *CRPS* include *hand-shoulder syndrome*, *sympathalgia*, *algodystrophy*, and *Sudeck atrophy*. A consensus conference held in Budapest in 1993 attempted to improve the diagnostic precision of these phenomena and renamed the condition "complex regional pain syndrome." CRPS I was intended to replace the term *reflex sympathetic dystrophy* and CRPS II to replace "causalgia." These changes were an attempt to eliminate the requirement that involvement of the sympathetic nervous system is necessary for the generation of symptoms. Clinical studies suggest that between 25% and 35% of individuals with CRPS have sympathetically maintained pain.

EPIDEMIOLOGY

In two population-based studies, the incidence of CRPS was estimated to range between 5.5 and 26.2 per 100,000 person-years. In Olmsted County, Minnesota, the prevalence was estimated at 20.6 per 100,000. A more recent study conducted by examining the Korea National Health Insurance Service reported an incidence of 28.0 to 32.4 per 100,000 person-years. Women are 3 times more likely to be affected, with postmenopausal woman having the highest risk. CRPS is most commonly diagnosed in middle age (40-60 y), with children and the elderly comprising smaller subsets. CRPS after an upper limb injury is more common than after a lower limb injury; following distal radius fracture, it occurs in more than one-fifth of individuals in some studies. There is some evidence that CRPS in children is associated with a more favorable prognosis.

CLINICAL FEATURES AND PATHOLOGY

CRPS I is a disorder characterized by pain that is disproportionate to the severity of the injury and accompanied by allodynia, vasomotor disturbances, motor disturbances, and/or trophic changes in the skin. Allodynia is defined as "pain resulting from a stimulus (such as lightly touching the skin) that would not normally provoke pain." The symptoms typically follow trauma, including mild trauma, but can occur after a myocardial infarction or varicella zoster infection. In approximately 10% of cases, the specific event is unknown. A bone fracture or other pathology requiring extremity surgery is the most common preceding event, occurring in about 45% of patients. The arm is affected more commonly than the leg.

The pain in CRPS is described by a multitude of terms, including "deep, sharp, sensitive, and hot." Patients, particularly those with sympathetically maintained pain, are often sensitive to cold sensations and frequently guard their limbs to avoid physical contact. Swelling, edema, heat, and color changes occur in the affected limb, which may be followed by osteoporosis and changes in hair, skin, and nail growth. The pain does not conform to a single nerve or root distribution and usually spreads beyond the area of injury. In more than 50% of cases, spread to a different extremity is noted, which sometimes occurs in a "mirror-image pattern." Some patients with CRPS I develop dystonic postures of a hand or foot. Features similar to psychogenic movement disorders have been noted by some authors, including difficulty initiating movement, chorea, and dystonia at rest. According to the most recent International Association for the Study of Pain (IASP) nomenclature, CRPS I is now classified as nociplastic pain. This category includes chronic pain syndromes not otherwise related to tissue insult or a somatosensory neural lesion. Some of the pathologic mechanisms implicated in nociplastic conditions include maladaptive cortical plasticity, central sensitization, decreases in the activity of descending inhibitory systems, and abnormal activity in the sympathetic nervous system.

CRPS II is defined by the presence of a nerve injury and consequently is categorized as neuropathic pain. Fewer than 10% of people with CRPS have CRPS II, with the most common etiology being missile injuries such as gunshot wounds.

In anatomic studies of a single autopsy case of a CRPS I patient, pathologic changes included loss of posterior horn cells and activation of microglia and astrocytes. These changes were most prominent at the site of injury but extended throughout the length of the spinal cord. A study of the remaining proximal limb after amputation, microvascular changes with thickened basal membranes in capillaries in muscle, and the loss of C fibers in some patients were noted. In skin biopsy, CRPS I, defined by the absence of an identifiable nerve injury, may show fewer small sensory epidermal nerve fibers than controls. In individuals with CRPS, functional magnetic resonance imaging has demonstrated cortical reorganization with shrinkage of the contralateral primary somatosensory cortex. These changes may reverse with pain relief.

PATHOBIOLOGY

There is little information about the pathophysiology of CRPS, with both peripheral and central neural mechanisms involved. Human leukocyte antigen associations have been described but not confirmed. Theories of the pathogenesis have centered on central sensitization, oxidative damage, and inflammation. After injury, an initial barrage of C fiber afferent activity may result in central sensitization (see Chapter 59) of dorsal horn neurons, resulting in allodynia and expansion of receptive fields. Patients with CRPS have increased levels of proinflammatory cytokines (interleukin [IL]-1β, IL-2, IL-6, tumor necrosis factor α) and markers of glial cell activation in the cerebrospinal fluid. An increase in markers indicating oxidative damage, including malondialdehyde, has also been reported, along with a loss of inhibitory dorsal horn neurons.

More recently, autoimmune mechanisms have been proposed. Studies have demonstrated autoantibodies to autonomic nervous system autoantigens in 30% to 40% of CRPS patients but not in control or neuropathy patients. Immunoglobulin G antibodies to autonomic receptors (β_2-adrenergic receptor and muscarinic-2 receptor) have also been demonstrated. Upregulation of α_1-adrenoreceptors on nociceptive afferents present in the periphery may augment pain and neuroinflammation in CRPS. This may explain the increased pain response in individuals with CRPS after administration of norepinephrine and alleviation of pain after infusion of phentolamine, an α-blocker. As noted earlier, approximately 25% of people with CRPS display prominent sympathetically maintained symptomatology.

DIAGNOSTIC CRITERIA

In addition to changes in terminology, diagnostic criteria have also evolved. Early attempts to define diagnostic criteria were based on anecdotal accumulation of signs and symptoms. Kozin et al established diagnostic criteria in 1976, including categories for definite, probable, and doubtful RSD. Gibbons proposed a diagnostic scale based on clinical signs and symptoms and laboratory tests including response to sympathetic nerve block. Blumberg proposed a numeric grading scale based on autonomic symptoms, motor symptoms, and sensory symptoms. Still, others described stages of RSD, with early stages being categorized as "warm" (associated with increased blood flow and edema), middle stages as "cool" (characterized by vasoconstriction and decreased temperature), and later stages as atrophic (eg, brittle nails, osteoporosis).

The IASP diagnostic criteria for CRPS from Merskey and Bogduk (1994) include the following:

1. The presence of an initiating noxious event or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia in which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain
4. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction: type 1, without evidence of major nerve damage; type 2, with evidence of major nerve damage.

A consensus workshop convened in 2003 proposed changes to these criteria because of concerns that the earlier criteria lack specificity in the face of high sensitivity. Validation studies suggested that overdiagnosis was a problem and that the inclusion of objective data beyond subjective and historical data would improve specificity at the expense of only modest diminution in sensitivity.

The Budapest criteria were accepted by the IASP for the third revision of formal taxonomy and diagnostic criteria of pain states. Clinical diagnostic criteria for CRPS include an array of painful conditions characterized by continuing (spontaneous or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or dermatome) and typically shows a distal predominance of abnormal sensory, motor, sudomotor vasomotor, or trophic findings, all with variable progression over time. Clinically, CRPS I and II are indistinguishable.

Clinical Diagnostic Criteria

1. Continuing pain disproportionate to an inciting event
2. Must include at least one symptom in three of the four following categories:
   a. Sensory: hyperesthesia, allodynia, or both
   b. Vasomotor: temperature asymmetry, skin color changes, skin color asymmetry, or all of these
   c. Sudomotor/edema: edema, sweating, sweating asymmetry, or all three
   d. Motor/trophic: decreased range of motion, motor dysfunction (weakness, tremor, dystonic posture), trophic changes (hair, nail, skin), or all three
3. Must display at least one sign at the time of evaluation in two or more categories:
   a. Sensory: hyperalgesia (eg, to pinprick), allodynia (to light touch, temperature sensation, or deep somatic pressure or joint movement), or combinations of these
   b. Vasomotor: evidence of temperature asymmetry (>1°C), skin color changes or asymmetry, or combinations
   c. Sudomotor/edema: edema, sweating changes, or sweating asymmetry
   d. Motor/trophic: decreased range of motion, motor dysfunction (weakness, tremor, dystonia), or trophic changes (hair, skin, nails)
4. No other diagnosis better explains the sign and symptoms.

Research Diagnostic Criteria

1. Continuing pain disproportionate to an inciting event
2. Must include at least one symptom in each of the four following categories:
   a. Sensory: hyperesthesia, allodynia, or both
   b. Vasomotor: temperature asymmetry, skin color changes, skin color asymmetry, or all of these
   c. Sudomotor/edema: edema, sweating, sweating asymmetry, or all three
   d. Motor/trophic: decreased range of motion, motor dysfunction (weakness tremor, dystonic posture), trophic changes (hair, nail, skin), or all three
3. Must display at least one sign at the time of evaluation in two or more categories:
   a. Sensory: hyperalgesia (eg, to pinprick), allodynia (to light touch, temperature sensation, or deep somatic pressure or joint movement), or combinations of these
   b. Vasomotor: evidence of temperature asymmetry (>1°C), skin color changes or asymmetry, or combinations
   c. Sudomotor/edema: edema, sweating changes, or sweating asymmetry
   d. Motor/trophic: decreased range of motion, motor dysfunction (weakness, tremor, dystonia), or trophic changes (hair, skin, nails)
4. No other diagnosis better explains the sign and symptoms.

These criteria bear no relationship to etiology and have no known association with pathophysiology. Tests of these criteria demonstrated lower rates of overdiagnosis with little loss of sensitivity compared to the previously accepted IASP criteria.

Published data report that the clinical criteria result in a sensitivity of 85% and specificity of 69%, with the research criteria having a sensitivity and specificity of 70% and 95%, respectively, when compared to non-CRPS neuropathic pain disorders based on a CRPS database checklist consisting of signs and symptoms shown to be associated with CRPS but not incorporated in IASP diagnostic criteria. The more stringent criteria for research purposes, which is analogous to comparing selection criteria in a randomized trial compared to those used in clinical practice, prioritizes diagnostic specificity over sensitivity.

Other diagnostic tests employed to identify CRPS patients include thermography, triple-phase bone scans and other radiologic procedures, and quantitative sensory testing. All of these have been validated against a clinical diagnostic gold standard. Schurmann et al studied patients with acute radial fracture who met the 1994 IASP criteria and the 1999 Bruehl research criteria. Relative to a clinical diagnostic gold standard, they found that bone scans had high specificity but low sensitivity, making this a poor screening test. Results of thermography testing have demonstrated poor sensitivity and specificity. Similar to bone scanning, magnetic resonance imaging and plain x-rays yield high specificity but have poor sensitivity, with the positive and negative predictive values of plain films being 58% and 86%, respectively. The findings suggest that these tests are not useful for screening but may be indicated as selection tools for clinical trials (Table 58.1).

Historically, three stages of CRPS have been described. Recent analysis has not supported this categorization but has instead suggested three possible subtypes: (1) a self-limited syndrome with predominance of vasomotor signs, (2) a limited syndrome with predominance of neuropathic pain/sensory abnormalities, and (3) full-blown CRPS with a high degree of motor/trophic and disuse-related changes.

TABLE 58.1 The Accuracy of Diagnostic Tests for Complex Regional Pain Syndrome (CRPS)

Diagnostic Test	Accuracy	Comments
Bone scintigraphy	Low sensitivity, high specificity	Triple phase bone scan may be useful for research purposes.
Duplex ultrasound	Low sensitivity	May rule out deep vein thrombosis
Quantitative sensory testing	Pressure pain thresholds have moderate sensitivity and specificity compared to asymptomatic controls.	Lower thresholds increase sensitivity at the expense of specificity.
Electrodiagnostic testing	Low sensitivity for CRPS I, higher for CRPS II	May be useful in CRPS II; often used to rule out underlying nerve injury
Quantitative Sudomotor Axon Reflex Test	Intermediate sensitivity, high specificity when sudomotor changes are present	Sensitivity increases in individuals with sympathetically maintained pain
Resting sweat output	Intermediate sensitivity, high specificity when sudomotor changes are present	Sensitivity increases in individuals with sympathetically maintained pain
Radiographs	Low sensitivity	Osteoporosis present in <50% of cases
Magnetic resonance imaging	Low sensitivity; intermediate to high specificity	Can be used to detect or rule out soft tissue injury
Thermography	Low sensitivity and intermediate specificity	Sensitivity and specificity increase in the presence of vasomotor changes. >1°C change is considered significant.
Sympathetic blocks	Highly sensitive for sympathetically maintained pain; low to intermediate specificity	Lower volumes increase specificity, particularly for stellate ganglion blocks wherein spread to brachial plexus may occur. Validity dependent on technical success (ie, 2°C temperature increase) of block.
Intravenous phentolamine test	Lower sensitivity and higher specificity compared to sympathetic blocks for sympathetically maintained pain	Validity depends on increase in temperature; often associated with reflex tachycardia and hypotension.

MANAGEMENT

Because the etiologies of CRPS are multifarious and uncertain, and therapies have for the most part been anecdotally based rather than scientifically tested in placebo-controlled trials, the treatment of CRPS remains controversial (Table 58.2). In general, syndromes (eg, nociplastic pain conditions such as CRPS I, fibromyalgia, and irritable bowel syndrome) tend to have poorer prognoses than better defined disease entities. This may be attributable to lack of consistent and readily identifiable pathophysiologic mechanisms. This is because mechanistic-based treatment of pain is generally acknowledged to be more effective than etiologic- or disease-based treatment.

Physical Therapies

Physical therapy and functional restoration programs form the cornerstone of treatment for CRPS, and the use of procedural interventions and medications is often touted as a means to maximize functional restoration. Yet, current guidelines have been predominantly developed by consensus. A recent Cochrane review evaluating physiotherapies for chronic pain in CRPS found very low evidence to support clinically meaningful improvement with graded motor imagery and mirror therapy, with the evidence in favor of electrotherapy, multimodal physical therapy, and lymphatic drainage being either absent or unclear.

In clinical practice, physical therapies should employ progressive movement and limb usage, gradually increased load bearing, as well desensitization to a variety of sensory stimuli in individuals with allodynia and hyperalgesia. Nerve blocks, psychotherapy, cognitive behavioral techniques, and pharmacotherapy may be added to facilitate participation in occupational and physical therapy. Edema should be addressed with active motion and/or special garments. Overall, the goal of physical therapy is to progressively restore function through the use of desensitization techniques, increasing flexibility, edema control, range of motion exercises, stress loading (ie, scrubbing and carrying), interventions to promote normal postures and balance, and personalized vocational and functional rehabilitation.

Nonopioid Pharmacotherapy

Few placebo-controlled randomized trials of drug therapy for CRPS have been carried out, and current therapy is largely based

TABLE 58.2 Evidence for Treatments for Complex Regional Pain Syndrome

Treatment	Evidence	Comments
Physical and occupational therapy	Positive evidence, including for graded motor imagery and mirror therapy	First-line treatment with and without additional therapies
Bisphosphonates	Positive evidence	Both oral and intravenous formulations effective. The high doses clinically required may necessitate surveillance.
Acupuncture	Positive evidence	Useful with rehabilitation program
Neuromodulation	Positive evidence for spinal cord stimulation, dorsal root ganglion stimulation, transcutaneous electrical nerve stimulation, and repetitive transcranial magnetic stimulation	Transcutaneous electrical nerve stimulation may be used as first-line therapy in conjunction with physical therapy. Benefits decrease with time.
Corticosteroids	Positive evidence	For use in acute and subacute stages; may be more effective for CRPS II
Intravenous regional blockade	Positive for lidocaine and ketanserin; mixed for guanethidine and reserpine	Anecdotal evidence for labetalol, phenoxybenzamine, and clonidine
Intrathecal baclofen	Positive evidence	Based on a small, randomized trial, but a later trial demonstrated lack of dose-responsiveness
Intravenous therapies	Positive evidence for ketamine; negative for prolonged effect for lidocaine and IVIg	Evidence for dose-response effect with ketamine
Anticonvulsants	Positive for carbamazepine; mixed for gabapentin	Oxcarbazepine may be an alternative to carbamazepine based on similar mechanism of action and anecdotal evidence.
Antidepressants	Weak, positive evidence based on comparative-effectiveness study and guidelines	Tricyclic antidepressants and serotonin-norepinephrine reuptake inhibitors preferable over serotonin selective reuptake inhibitors and may be beneficial for concomitant depression and anxiety
Tadalafil	Positive evidence	May be more effective for "cold" CRPS
N-acetylcysteine	Positive	May be more effective for "cold" CRPS
Topical agents	Anecdotal for lidocaine; positive for dimethyl sulfoxide	Dimethyl sulfoxide may work better for "warm" CRPS.
Intravenous immunoglobulin	Mixed evidence	Largest study negative
Calcitonin	Mixed evidence	May be more effective in later stages
Psychological therapy	Anecdotal evidence	May be more effective in patients with psychiatric comorbidities
Sympathetic blocks	Negative evidence for intermediate or long-term benefit	May be useful to facilitate physical therapy or identify sympathetically maintained pain

Abbreviations: CRPS, complex regional pain syndrome; IVIg, intravenous immunoglobulin.

on treatment of neuropathic pain. As noted earlier, CRPS I is now considered to be in a separate category of pain termed *nociplastic*. Although nociplastic pain shares many mechanisms with neuropathic pain (eg, peripheral and central sensitization, diminished inhibitory activity, sympathetic overactivity), it does not involve direct nerve injury. Consequently, there is significant overlap between nociplastic and neuropathic pain conditions.

Bisphosphonates including clodronate and alendronate, have demonstrated efficacy in the treatment of CRPS I in several moderate- to high-quality placebo-controlled trials, with the evidence supporting calcitonin being mixed. One systematic review evaluating bisphosphonates that identified four moderate- to high-quality studies containing 181 individuals found moderate evidence for efficacy in the treatment of pain and quality of life for up to 3 months. Both intravenous (IV) and oral steroids (eg, methylprednisolone 32 mg for 2 wk, then tapering off for 2 wk or prednisone 30 mg for 12 wk) have been shown to be more effective than placebo, with their use generally limited to individuals with acute or subacute pain.

The anticonvulsants gabapentin, pregabalin, and carbamazepine (for trigeminal neuralgia) are first-line treatments for neuropathic pain, and there is substantial anecdotal evidence for their benefit in CRPS. A randomized, double-blind crossover trial that compared carbamazepine to morphine in 43 patients with CRPS I who underwent temporary deactivation of a working spinal cord stimulation found carbamazepine to be superior to morphine.

A randomized crossover study was performed comparing 1,800 mg/d of gabapentin to placebo in 58 individuals with refractory CRPS I, yielding mixed results. Although gabapentin proved superior to placebo at the end of the first 3-week treatment period, there was no significant difference between treatment groups when both periods were combined. A more recent randomized trial performed in 34 children with CRPS I or a neuropathic pain condition found similar effectiveness for gabapentin and amitriptyline for pain reduction and sleep improvement. No placebo-controlled trials have been conducted evaluating antidepressants, although tricyclic antidepressants and serotonin-norepinephrine reuptake inhibitors such as duloxetine and venlafaxine are considered first-line treatments along with the gabapentinoids for neuropathic pain.

Opioid Treatment

Opioids have been anecdotally reported to provide benefit for CRPS I, but their use is not supported by clinical trials. In the only randomized trial evaluating opioids, carbamazepine was found to provide superior pain reduction than oral morphine 90 mg/d over an 8-day period of deactivation of previously effective spinal cord stimulation. Given the high risks of opioid therapy, lack of documented long-term benefit compared to nonopioid therapy, and the relative refractoriness to treatment of neuropathic and nociplastic conditions to opioid therapy, there is only a weak recommendation for use for neuropathic pain by the IASP Neuropathic Pain Special Interest Group. If considered, they should be instituted only with careful risk stratification, clearly defined benchmarks for success, a drug monitoring strategy, and a predefined exit strategy.

Topical Creams

Topical agents such as dimethyl sulfoxide and topical lidocaine have been successfully used for CRPS, with only the former demonstrating benefit in a randomized trial. In this double-blind comparative-effectiveness study, dimethyl sulfoxide was found to work better for "warm" CRPS, whereas oral *N*-acetylcysteine proved more effective for "cold" CRPS. For compounded pain creams containing multiple analgesic substances (eg, ketamine, gabapentin, muscle relaxants, lidocaine, nonsteroidal anti-inflammatory drugs), a recent placebo-controlled study that randomized patients according to their classification of pain (eg, neuropathic, nonneuropathic, or mixed) found no significant benefit for a variety of different pain conditions, including CRPS.

Continuous Infusion Therapy

Infusion therapy has been implemented for CRPS but is limited by resource requirements, reimbursement concerns, and the duration of benefit. In a randomized controlled trial comparing 4 weekly IV lidocaine infusions (3 mg/kg) to saline administration in 42 patients with CRPS II or postherpetic neuralgia, Kim et al reported benefit favoring lidocaine immediately after the third and fourth infusions, but the relief did not persist at 1- or 4-week follow-ups. Two randomized controlled trials evaluated ketamine infusions for CRPS. In a study by Schwartzman et al evaluating an outpatient regimen with doses titrated up to 100 mg over 4 hours, the authors found small benefits favoring ketamine through 12-week follow-up that fell shy of statistical significance. The lack of significance was attributed to the low dosage used and the small number of participants enrolled (n = 19) because the study was terminated early. Another study by Sigtermans et al that evaluated an inpatient, 100-hour infusion reported significant benefit favoring ketamine that persisted for 8 weeks. However, in a meta-analysis evaluating IV ketamine infusions, Orhurhu and colleagues found no difference in response rate between CRPS and non-CRPS patients, or when the pain condition was broken down by category (ie, neuropathic vs nonneuropathic vs nociplastic). Recent multispecialty guidelines on IV ketamine infusions found that moderate evidence supporting ketamine infusions to improve pain for up to 12 weeks (grade B recommendation, low-to-moderate level of certainty) as well as evidence to support higher doses.

Intravenous Therapies and Intravenous Regional Blockade

A systematic review was published in 2016 evaluating IV therapies for CRPS I and II. Based on their review of the literature, the authors found strong evidence for bisphosphonates; mixed evidence for magnesium; mixed evidence for nonsteroid anti-inflammatory drugs; negative evidence for mannitol and tumor necrosis factor α inhibitors; weak (ie, positive flawed randomized trials) evidence for immunoglobulin; weak evidence for IV regional blockade (IVRB) with lidocaine and ketanserin; mixed evidence for IVRB with the sympatholytic drugs guanethidine and reserpine; and anecdotal (ie, uncontrolled studies) evidence for IVRB with clonidine, phenoxybenzamine, and labetalol. In a randomized, placebo-controlled, double-blind study, intravenous immunoglobulin 0.5 g/kg was not effective.

Sympathetic Blocks and Sympathectomy

A recent Cochrane review evaluated the effectiveness of sympathetic blocks. Among the 12 trials (n = 461) evaluated, 3 were placebo-controlled, with 2 reporting no benefit; the 1 that did

report benefit found no short-term benefit for thoracic sympathetic blockade but significant improvement compared with placebo at 1 year. Among the 2 studies that compared add-on sympathetic blockade to active rehabilitation, the only study that reported pain outcomes found no benefit. In the 8 studies that compared sympathetic blocks to other active treatments, most found no differences in pain outcomes. Overall, the authors concluded that the paucity of high-quality studies precluded drawing firm conclusions regarding the efficacy or lack thereof of sympathetic blocks for CRPS but that the limited data available did not support the routine use of local anesthetic sympathetic blocks. In individuals who do respond with good, albeit temporary, relief from sympathetic blocks, chemical (eg, clonidine) or surgical sympathectomy can be considered, although a recent systematic review found that the practice was based on scant high-quality evidence. Although sympathetic blocks have sometimes been used to provide a short- or intermediate-term window to optimize physical therapy including desensitization, the benefit from multiple blocks must be carefully weighed against the significant risks and costs.

Neuromodulation

Transcutaneous electrical nerve stimulation and repetitive transcranial magnetic stimulation have been shown in randomized trials to provide benefit. For spinal cord stimulation, there is evidence in the form of randomized and numerous uncontrolled studies for intermediate-term benefit, although the beneficial effects wane over time, and there is inconclusive evidence for functional and psychological improvement. Recently, the use of dorsal root ganglion stimulation was shown in two randomized trials to be superior to conventional dorsal column stimulation.

Pain Prevention

There are many risk factors for the persistence of pain after injury, including female gender, opioid use, young age, the extent and type of trauma, magnitude of acute pain, psychiatric factors such as catastrophizing, anxiety and depression, sleep abnormalities, genetics, and secondary gain. Because trauma is unpredictable, and many of the risk factors are unalterable (eg, gender, age) or require intensive resources (eg, psychological factors, sleep abnormalities), it is unlikely that CRPS can be reliably prevented. However, because of the high incidence following predictable (ie, surgical) trauma, efforts have been made to reduce the chance of developing CRPS. Given its neuroprotective and neuromodulary antioxidant properties, the use of vitamin C to reduce postsurgical pain and prevent CRPS has been extensively studied. In a systematic review, Chen et al found moderate-level evidence for the preoperative use of vitamin C to reduce postsurgical pain and opioid consumption and high-level evidence to support the use of vitamin C (1 g/d × 50 d) to reduce the incidence of CRPS after extremity surgery.

FUTURE RESEARCH

An inability to identify distinct mechanisms for CRPS is not synonymous with the absence of mechanisms (Table 58.3). In general syndromes, which do not have reliably recognizable mechanisms but rather constitute a constellation of signs and symptoms in the absence of another explanation, tend to be associated with poorer outcomes than diseases, which contain mechanisms that can be readily identified and directly addressed (eg, immunosuppressive therapy for autoimmune diseases, anti-inflammatory therapy for inflammatory diseases). Although considerable overlap in mechanisms has proved challenging for directing treatment, more research is necessary in categorizing CRPS because the evidence seems to support different treatments for different subtypes (eg, cold vs warm).

TABLE 58.3 Potential Mechanisms for Complex Regional Pain Syndrome

Peripheral sensitization
Central sensitization
Decreased inhibitory control
Nerve injury
Oxidative stress
Altered sympathetic nervous system function and sympatho-afferent coupling
Cortical and spinal reorganization
Inflammatory mediators
Immune dysfunction (eg, glial cells)
Altered cutaneous innervation
Psychological vulnerability
Genetics
Disuse

To date, there has been little incentive for industry to conduct large randomized trials evaluating pharmacologic treatments for CRPS, and the efficacy studies that have been conducted tend to have stringent selection criteria that limits generalization. Large-scale registries, as has been recommended by the NIH Pain Research Strategy, may allow researchers and clinicians to identify phenotypes of individuals who may respond to different treatments and to better assess effectiveness in large populations, which may inform clinical trials.

Neuromodulation is a rapidly evolving area that has experienced enormous growth, to include high-frequency stimulation, burst stimulation, and stimulation involving different targets (deep brain and motor cortex, peripheral nerves and plexuses, nerve roots and dorsal root ganglia). Comparative-effectiveness studies are needed to determine the relative effectiveness of these therapies and whether different subtypes of CRPS may respond differently.

Finally, preventive therapies in individuals at high risk for CRPS should be further studied to include psychological interventions in individuals with coexisting psychopathology, minimally invasive surgeries, and multimodal therapies.

CONCLUSIONS

CRPS is a challenging condition, with its classification as a syndrome posing particular barriers to treatment because treatment is predominantly empirically based, rather than based on mechanisms. Recently, CRPS I was reclassified as "nociplastic pain" given the overwhelming evidence in support of a primary disorder of central and peripheral pain processing. In contrast,

CRPS II remains a neuropathic pain condition, although clinically, the two conditions are clinically indistinguishable, with significant overlap in purported mechanisms. The diagnosis of CRPS is based on clinical signs and symptoms in the absence of other explanatory conditions, although certain diagnostic tests may be useful to enhance specificity for research purposes, to identify subtypes (eg, sympathetically maintained vs sympathetically independent pain), and to rule out alternative causes such as nerve entrapment. Physical therapies remain the cornerstone of treatment, although medications and procedures may be used to facilitate rehabilitation. Among pharmacologic treatments, the strongest evidence is for bisphosphonates, although the randomized trials evaluating their use are generally small and methodologically flawed. Neuromodulation in the form of spinal cord stimulation, and more recently dorsal root ganglion stimulation (which has been shown in some studies to be superior to conventional dorsal column stimulation), should be considered for refractory cases. Future research should consider preclinical studies focusing on identification of mechanistic subtypes, registries that seek to determine large population-based outcomes and identify phenotypes that may favorably respond to different treatments, and the indications and effectiveness for preventative measures such as vitamin C before high-risk surgery.

Neuropathic Pain 59

Jeffrey Shije and Thomas H. Brannagan III

KEY POINTS

1. Nociceptive pain serves a protective function. However, pathology of the somatosensory nervous system may result in neuropathic pain, which no longer serves that purpose.
2. In response to disease or injury, there are complex mechanisms that lead to sensitization of the peripheral and central nervous system, resulting in maladaptive pain.
3. Neuropathic pain is suspected based on symptomatic features (ie, numbness, paresthesia, spontaneous pain, allodynia, etc) and should have some neuroanatomic correlation with the underlying pathology. The initial step of diagnosis is to identify the underlying cause.
4. In addition to addressing the underlying cause, there are pharmacologic treatments for neuropathic pain, supported by various levels of evidence. Ongoing research is needed for treatments that produce better outcome.

INTRODUCTION

Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. For the discussion of pain, it is important to be familiar with certain key terms, outlined in **Table 59.1**. Nociceptive pain has a protective function because it warns of injury or impending injury. Sensitization of peripheral nociceptors and central nervous system changes occur, protecting the damaged area, by avoiding contact. However, pathology of the nervous system may result in a maladaptive pain that no longer correlates with injury or disease activity. Neuropathic pain is a maladaptive pain, which results from nervous system damage and pain in the absence of nociceptor stimulation or an inappropriate response to nociceptor stimulation. Nociceptive and neuropathic pains are not synonymous with acute and chronic pain. Rheumatoid arthritis, for example, is a chronic pain, which is nociceptive. A herniated disk may acutely cause radicular pain, which is neuropathic. The International Association for the Study of Pain (IASP) defines neuropathic pain as pain caused by a lesion or disease of the somatosensory nervous system, although other more inclusive definitions exist. With neuropathic pain, in addition to sensory impairment, there are coexisting abnormal sensory symptoms (see **Table 59.1**). Once developed, these types of pain may persist even after resolution or adequate management of the underlying pathology, making the treatment of neuropathic pain relatively challenging. This chapter reviews the normal neurologic processing of nociception, the proposed mechanisms that give rise to neuropathic pain, its clinical relevance and treatment approaches, with a particular emphasis on painful neuropathy.

TABLE 59.1 Key Pain Terminology[a]

Nociceptive pain: pain that arises from actual or threatened damage to nonneural tissue and is due to the activation of nociceptors
Neuropathic pain: pain caused by a lesion or disease of the somatosensory nervous system
Allodynia: pain due to a stimulus that does not normally provoke pain
Hyperalgesia: increased pain from a stimulus that normally provokes pain
Paresthesia: an abnormal sensation, whether spontaneous or evoked (ie, tingling, crawling)
Dysesthesia: an unpleasant abnormal sensation, whether spontaneous or evoked (ie, paresthesia that is painful)
Sensitization: increased responsiveness of nociceptive neurons to their normal input and/or recruitment of a response to normally subthreshold inputs (may occur in peripheral and/or central nervous system)
Neuralgia: pain in the distribution of a single peripheral nerve
Neuropathy: a disturbance of function or pathologic change in peripheral nerves. (Mononeuropathy involves one nerve. Mononeuropathy multiplex involves several different nerves. Neuropathy is often used interchangeably with polyneuropathy; however, polyneuropathy is reserved for when the neuropathy is due to a diffuse disease process.)

[a]Adopted from Merskey H, Bogduk N. *Classification of Chronic Pain: Descriptions of Chronic Pain Syndromes and Definitions of Pain Terms.* 2nd ed. Seattle, WA: International Association for the Study of Pain; 1994.

EPIDEMIOLOGY

The challenge of estimating the prevalence of neuropathic pain stems from the fact that it is a clinical feature of a wide variety of different neurologic disorders. Often, it is described or categorized based on the underlying disease. For example, the prevalence of neuropathic pain due to diabetic neuropathy has been reported to range from 11% to 28%; neuropathic pain in cancer patients ranged from 18% to 21% in the United Kingdom. On the other hand, neuropathic pain may also be categorized based on clinical features (ie, numbness, burning, tingling, pins and needles, electric shock, etc) independent of the underlying cause. In a large survey using a validated neuropathic pain screening tool, the painDETECT questionnaire, which is based on abnormal sensation and pain characteristics, it was estimated that the prevalence of neuropathic pain in the United States was about 10%.

PATHOBIOLOGY

Normal Processing of Nociceptive Pain

In order to appreciate the neuroplastic changes that occur in neuropathic pain, one must be familiar with the normal processing of nociceptive pain, which can be described in a series

of events: (1) transduction of the noxious stimulus into electrical signal, (2) transmission of the electrical signal from peripheral to central nervous system, (3) modulation of the nociceptive signal, and ultimately (4) the perception of painful experience.

Transduction and Transmission

In general, nociceptors are high-threshold sensory receptors at the peripheral nerve endings that are activated by noxious stimuli (ie, thermal, chemical, mechanical), leading to depolarization of the distal nerve fibers. The axons of these nerve fibers belong to the first-order sensory dorsal root ganglion (DRG) neurons. The conversion of nonelectrical signals to electrical signals by nociceptors is termed *transduction*.

The resulting action potential is then transmitted via the peripheral axon of the DRG neuron to the dorsal horn of the spinal cord, to synapse with the second-order nociceptive neurons there. The DRG neurons can be classified by the degree of myelination and the conduction speed of their axon fibers. The heavily myelinated, rapidly conducting, low threshold Aβ-fibers are typically nonnociceptive. Those with nociceptive functions consist of the thinly myelinated, slower conducting, small-diameter Aδ-fibers and the unmyelinated, very slowly conducting, very-small-diameter C fibers. Aδ-fibers may transmit the initial sharp pain, whereas C fibers may transmit heat or the subsequent lingering pain.

If a noxious stimulus results in tissue damage, there may be erythema and edema, mediated by local proinflammatory factors (ie, histamine, bradykinin, prostaglandin, cytokines, etc). These proinflammatory mediators are sometimes referred to as *inflammatory soup*, which may sensitize the peripheral nociceptors, resulting in increasing firing at lower thresholds to less intense stimuli. Some of the nociceptive action potential may even rebound antidromically through other axonal branches back to the site of injury and release more proinflammatory mediators, in a process called *neurogenic inflammation*. Ultimately, nociceptive action potentials reach the spinal cord and release pronociceptive neurotransmitters such as substance P and calcitonin gene-related peptide to activate the second-order nociceptive neurons in the dorsal horn of the spinal cord.

The second-order nociceptive neurons in the dorsal horn project axons that cross midline via the anterior white commissure to travel with the contralateral spinothalamic tract and ultimately reach the contralateral ventroposterolateral thalamus. From there, third-order neurons convey primary nociceptive information through the posterior limb of the internal capsule to the postcentral gyrus (primary somatosensory cortex).

Modulation and Perception

The transmitted nociceptive signals may be modulated at the level of the dorsal horn, by descending pathways in the spinal cord, or in the brain.

The dorsal horn of the spinal cord is organized into layers called *Rexed laminae*. Aδ-fibers largely terminate in lamina I (the marginal zone), which is the most dorsal layer, although some also project to lamina V. Most of the C fibers terminate in lamina II (ie, substantia gelatinosa). These lamina layers contain complex networks of interneurons that have excitatory and inhibitory functions that modulate the transmission of nociceptive signals form the DRG to the dorsal horn neurons.

Nociceptive transmission in the dorsal horn is also influenced by descending modulatory mechanisms. A well described example of these mechanisms involves the periaqueductal gray (PAG) in the dorsal midbrain and the rostral ventromedial medulla (RVM). The PAG-RVM system receives inputs from spinothalamic tract and cortical projections and sends descending projections to the dorsal horn of the spinal cord. Norepinephrine, serotonin, γ-aminobutyric acid (GABA), as well as enkephalins (or endogenous opioids) play important roles in the inhibitory effect of the descending modulatory systems.

Ultimately, the perception of pain is produced in the brain by integrating the somatosensory, cognitive, and affective components of the experience. Functional magnetic resonance imaging studies have shown that during painful experiences, areas of increased metabolic activity include those involved in sensory processing, that is, ventrolateral thalamus and somatosensory cortex as well as those involved in emotional processing and integration, that is, anterior cingulate and insular cortex.

Mechanisms Underlying Neuropathic Pain

Unlike nociceptive pain, neuropathic pain no longer serves a protective purpose. Instead, it causes physical suffering and emotional distress without obvious benefit. The mechanisms underlying this maladaptive pain are complex and are thought to give rise to peripheral and central sensitization, as discussed in the following text.

Peripheral Sensitization

Pathology of the peripheral nervous system may take place at the level of the nerve, plexus or nerve root, and may be due to mechanical, inflammatory, toxic, or other etiology. Consequently, there may be increased nerve membrane potential excitability at the terminal nociceptors or proximal to them. When electrical impulses are generated from locations other than the terminal nociceptors, they are referred to as *ectopic discharges*. Ectopic discharges can be generated spontaneously or triggered by previously subthreshold stimuli.

Depending on the nature of the nerve damage, ectopic discharges may be generated from neuroma, axon segments or the DRG soma. For example, transection of a nerve is often followed by axonal sprouting from the proximal nerve stump in an attempt for regeneration; if these sprouts fail to enter a Schwann cell tube in the distal nerve segment, they may form a neuroma. (Trauma over the length of a nerve, even without transection may damage small axon fascicles and lead to formation of microneuromas.) Neuromas have been shown to be a source of ectopic discharges and electrical pacemaker activity. More proximally, axonal or demyelinating injuries of the nerve segments may lead to ectopic discharges, and these can spread to adjacent uninjured afferent axons by a process called *ephaptic transmission*. In some cases, these electrical currents may be sustained in a closed-circuit loop. Furthermore, adjacent uninjured axons, attempting to reinnervate the denervated areas, may produce collateral sprouts that may be hyperexcitable as well. Lastly, there is evidence from animal models of nerve injury that the DRG itself can be a source of ectopic discharges. For example, spinal nerve injury lead to increased subthreshold membrane potential oscillations in DRG neurons, and these oscillations often trigger bursts of action potentials.

Injury to the peripheral nervous system often results in the release of various inflammatory mediators and growth factors, which may alter the expression, distribution and posttranslational modification (ie, phosphorylation) of various ions channels that lead to nerve membrane potential hyperexcitability. Some of these ion channels are described in the following text.

Sodium Channels

Immunofluorescent labeling of injured nerve fibers has demonstrated that sodium ion channels can accumulate in demyelinated nerve segments, new axonal sprouts, or end-bulb neuroma. Furthermore, there are both down- and upregulation of various sodium ion channels after nerve injury. Among these, the voltage-gated sodium channel (Na_v)1.3 is typically not expressed in adult DRGs but is upregulated after nerve injury. Also, Na_v1.8 is predominantly expressed in nociceptors, and its levels are increased in axonal membrane after nerve injury. The reexpression of Na_v1.3 and increased expression of Na_v1.8 are seen in adjacent uninjured axons as well. Na_v1.7 expression is not increased in nerve injury nor predominantly expressed in nociceptors, but a gain of function mutation of Na_v1.7 can result in abnormal pain syndromes. These sodium ion channels would seem to be ideal therapeutic targets, but it was demonstrated that knockout of Na_v1.3, 1.7, and 1.8 in mice did not prevent the development of neuropathic pain behaviors, suggesting that the development of neuropathic pain does not depend solely on changes in sodium channel expression.

Potassium Channels

Potassium channels play important roles in stabilizing neuronal membrane potentials. One example of these is TRESK, a two-pore-domain potassium channel, which is highly expressed in the DRG. TRESK is downregulated after nerve injury, leading to decreased membrane potential stability. Another example is the low-voltage-activated K^+ channels, which are also downregulated in nerve injury. Opening these channels has been shown to have antinociceptive effects in animal models of neuropathic pain.

Calcium Channels

N-type calcium channels are present at high levels in the presynaptic terminals of DRG neurons. Influx of calcium ions through these channels leads to membrane depolarization and release of pronociceptive neurotransmitters from DRG to dorsal horn neurons. N-type calcium channels, particularly their $\alpha 2\delta$ subunits, are upregulated following nerve injury, further promoting transmission of nociceptive signals from the DRG to the dorsal horn neurons. It is believed that the gabapentinoids exert their effect in neuropathic pain by binding and interfering with the $\alpha 2\delta$ subunits of the N-type calcium channels.

Other Ion Channels

Vanilloid receptor 1 (TRPV1) is a nonselective cation channel that can be activated by various stimuli such as heat, low pH, and various chemical compounds including capsaicin. It is primarily expression on C- and Aδ-fibers, and its activation can produce painful and burning sensation. In response to nerve injury, Vanilloid receptor 1 expression may be increased, and the threshold for channel activation may be decreased. DRG neurons also express hyperpolarization-activated cyclic nucleotide-gated (HCN) channels (HCN1 in large DRG neurons and HCN2 in small DRG neurons), which generate slowly depolarizing currents. These channels open in response to hyperpolarization overshoot during the refractory phases of an action potential, thus allowing subsequent depolarization to occur. Expression of HCN channels is increased after peripheral nerve injury in rats, contributing to increased membrane potential oscillation in the DRG and subsequent ectopic discharges.

Regardless of the location or mechanism of the ectopic impulse generation, the frequent or unrelenting nociceptive input from the peripheral nervous system to the spinal cord further promotes sensitization of the central nervous system.

Central Sensitization

In theory, nociceptive potentials may be independently generated in the central nervous system. Here, we will primarily discuss central sensitization that occurs in response to nerve injury. This sensitization is the result of various changes (neuroplasticity) in the central nervous system that include a form of long-term potentiation (windup), increased nociceptive field of the dorsal horn neurons, sensitization of low-threshold Aβ fibers, and decreased inhibitory modulations.

Enhanced Windup

Repetitive nociceptive input from the DRG to the dorsal horn neuron can lead to increased synaptic strength, a form of long-term potentiation. One example of this is the phenomenon of windup, where C fiber firing at a low frequencies and repetitive train, can result in a progressive buildup response amplitude of the dorsal horn neuron. One proposed mechanism is that repetitive stimulation of the dorsal horn neuron by C fibers cause its membrane potential to be increasingly depolarized through activation of *N*-methyl-D-aspartate (NMDA) receptors. Consequently, increased intracellular calcium ions may activate protein kinase C, which further promotes calcium influx via NMDA ionophores or other calcium channels, promoting further depolarization. Windup is not necessarily pathologic, but it can be enhanced as a result of nerve injury–induced neuroplasticity, such that stronger temporal summation, higher amplitude, and longer duration of postsynaptic potentials are now featured in the windup process.

Altered Receptive Field

It is not uncommon for patients to report neuropathic pain in locations beyond the dermatomal representation of their nerve injury. One feature of central sensitization is that the nociceptive dorsal horn neurons now respond to peripheral inputs outside of their previous somatotopic field. After peripheral nerve injury, the aberrant rerouting of impulses within the spinal cord may result in the diversion of impulses from nonnociceptive pathways to nociceptive pathways. This has been demonstrated animal experiments, where evoked dorsal horn neuron activity may be induced by nonnociceptive stimulation of areas supplied by an uninjured nerve, suggesting spread of nonnociceptive impulses from normal routes into nociceptive pathways. This type of somatotopic reorganization could result from limited axonal sprouting over short distances within the dorsal horn of spinal cord, where formation of new synapses is prompted when primary sensory input is interrupted. However, this is not the only explanation.

Sprouting Versus Unmasking of Previous Synapses

A key feature of central sensitization is that the low-threshold Aβ-fibers are now able to trigger excitatory responses in the nociceptive dorsal horn neurons. This challenges the traditional understanding that the Aβ-fibers do not transmit nociceptive signals. One hypothesis for this phenomenon is that the low-threshold Aβ-fibers, which had few or no synapses to the superficial lamina (I and II) of the dorsal horn, are now able to sprout into the superficial lamina to synapse with the nociceptive

neurons there, in response to nerve injury. (Demonstrated by a retrograde axon tracer labeling of Aβ-fiber in superficial lamina after nerve injury, but later evidence suggested this may be due to C fiber phenotypic switching rather than Aβ-fiber sprouting.) Another hypothesis is that there are previously quiescent, polysynaptic pathways from the low-threshold Aβ-fibers to the superficial lamina, and these pathways are "unmasked" in response to nerve injury. Consequently, a nociceptive field may be broadened, and a previously nonnociceptive stimulus may now produce pain (ie, allodynia). Perhaps, decreased inhibition from the spinal cord interneurons and descending inputs contribute to the "unmasking" of these previously silent synapses.

Loss of Inhibition

Normally, inputs from the DRG to the dorsal horn neurons are under regulation by pre- and postsynaptic inhibitory inputs from spinal cord interneurons and descending pathways (ie, PAG and RVM). There is evidence that these inhibitory effects are reduced in peripheral nerve injury. For example, many of the interneurons use GABA as an inhibitory neurotransmitter, and a reduction of GABA in the spinal cord dorsal horn was demonstrated in chronic constriction and spared nerve injury models in animal experiments. There is evidence that repeated Aδ-fiber inputs to the dorsal horn may promote neuronal apoptosis, possibly through an excitotoxic mechanism, such as those mediated by excessive glutamate receptor activation. Furthermore, those experiments demonstrated that the nerve injury–induced neuronal apoptosis in the dorsal horn correlated with a reduction of GABA content and GABA-producing enzyme in the dorsal horn.

Microglia Mediated Hypersensitivity

Spinal glial cells, that is, microglia, are activated in response to nerve injury and produce proinflammatory cytokines and chemokines. These inflammatory mediators can induce hyperexcitability in nociceptive dorsal horn neurons and reduce inhibitory regulations, contributing to central sensitization.

DIAGNOSIS

In the clinical setting, there are no methods to determine whether an individual's pain is purely nociceptive or modified by sensitization. The suspicion of neuropathic pain is primarily based on the patients' description of pain and sensory abnormalities (ie, tingling, burning, electric shock, numbness, etc). There are neuropathic pain screening tools such as the painDETECT questionnaire that use these descriptive features to determine the likelihood of neuropathic pain. However, these are not diagnostic tools for the cause of neuropathic pain.

Because neuropathic pain can be a feature of various neurologic disorders, the initial step of diagnosis is to evaluate for any underling pathology; that is, is there objective evidence of mononeuropathy, polyneuropathy, radiculopathy, plexopathy, or pathology of the central nervous system? If so, how likely is it that the pain (and sensory symptom) is due to a direct consequence of the lesion or disease affecting the somatosensory nervous system? Based on this concept, a grading system for the diagnosis of possible, probable, and definite neuropathic pain has been proposed by the IASP for research and clinical use.

There are three distinct anatomic patterns of peripheral neuropathy: *mononeuropathy, mononeuropathy multiplex, and polyneuropathy*. Mononeuropathy may produce decreased sensation in the receptive sensory field of the nerve and/or weakness in the muscles it innervates, although the associated pain may extend beyond its normal receptive field (a feature of central sensitization). Mononeuropathy multiplex may produce deficits that correspond to the distributions of multiple individual nerves. Polyneuropathy implies a more diffuse involvement of the peripheral nerves. It may be length dependent or non–length dependent. When the sensory component is involved, length-dependent polyneuropathy produces numbness and often neuropathic pain in a stocking and glove distribution (feet, distal legs and hands, with feet often being the initial sites of symptoms, and leg and hands may be involved as the polyneuropathy progresses). Non–length-dependent polyneuropathies produce symptoms that may be asymmetrical or patchy. Examples of various causes of peripheral neuropathy are listed by anatomic pattern in **Table 59.2**. Similarly, neuropathic pain due to disease or injury of the nerve root, plexus, and the central nervous system that produce sensory deficits should have some neuroanatomic correlation. For example, even though the foot/leg pain from an L5 radiculopathy may be referred beyond the borders of the L5 dermatome, any correlating sensory deficit should still be within the corresponding dermatome.

The primary aim of diagnostic testing is to evaluate for evidence of underlying localization and etiology of the neuropathology. Nerve conduction study and electromyography can help demonstrate electrophysiologic evidence of mononeuropathy, polyneuropathy, plexopathy, or radiculopathy. In scenarios where polyneuropathy is suspected but is not demonstrated by nerve conduction study, other options such as skin biopsy and quantitative sudomotor axonal reflex test may provide evidence of small fiber neuropathy. Additional laboratory testing

TABLE 59.2 Causes of Painful Neuropathy by Anatomic Distribution

Mononeuropathy	Mononeuropathy Multiplex (multiple individual nerves)	Polyneuropathy (length dependent, symmetrical, stocking and glove pattern)
• Compressive (carpal tunnel syndrome, ulnar neuropathy at the elbow) • Trauma • Neoplastic	• Diabetes • Vasculitis • Sarcoidosis	• Diabetes/prediabetes[N,S] • Chemotherapy induced • Gammopathy (including POEMS syndrome) • Vitamin deficiency/toxicity (B_{12} deficiency, B_6 deficiency and toxicity) • Infectious (ie, HIV, shingles, Lyme disease) • Primary autoimmune (ie, GBS, CIDP) • Secondary autoimmune (ie, Sjogren sydrome,[N,S] celiac, lupus, Wegner, and other vasculitides[N]) • Amyloid (ie, AL, hATTR) • Paraneoplastic (ie, Anti-Hu) • Hereditary (ie, HSAN, Fabry cisease)[S]

Abbreviations: AL, light-chain amyloid; CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; GBS, Guillain-Barré syndrome; hATTR: hereditary transthyretin amyloidosis; HIV, human immunodeficiency virus; HSAN, hereditary sensory autonomic neuropathy; [N], can be non–length dependent; POEMS, polyneuropathy organomegaly, endocrinopathy, M protein, skin changes; [S], can be small fiber predominant.

and when appropriate, nerve biopsy, are used to determine the etiology of the neuropathy. Imaging tests such as magnetic resonance imaging can be used to evaluate for certain causes (ie, mass lesion, compression, evidence of inflammatory) of neuropathy, plexopathy, radiculopathy, or pathology of the central nervous system (ie, multiple sclerosis, stroke, etc). Blood-based diagnostic tests can help establish metabolic (ie, diabetes, vitamin deficiency, etc), infectious (ie, Lyme disease), autoimmune, or paraneoplastic syndromes (refer to Chapters 90 and 91).

MANAGEMENT

General Principles

In general, the goal of management is to detect and treat any underlying pathology associated with the pain. If there is no treatment for the underlying pathology, or if the neuropathic pain become persistent despite resolution or adequate control of the underlying pathology, then the treatment of the pain itself becomes a focus of management. Although some patients may have complete resolution of their pain with treatment, most do not. Realistic expectations should be set early. If complete pain resolution is not achieved with available treatment options, the goal of care may be to reduce pain severity, promote physical function, and improve mood and sleep. Furthermore, it should be emphasized that neurologic symptoms such as loss of sensation, weakness, and other deficits are not expected to improve from medications meant to reduce neuropathic pain.

Pharmacologic Treatments

Historically, clinical trials for neuropathic pain have been based on the underlying etiology of the peripheral neuropathy (ie, evaluating pain treatments in diabetic neuropathy or postherpetic neuralgia, etc). It has been suggested that the mechanisms of neuropathic pain should be incorporated into the design of clinical trials, although this has been difficult to achieve. Current evidence supporting the use of various pharmacologic treatment come from randomized controlled trials (RCTs) of treatments for various painful neuropathies such as diabetic neuropathy, postherpetic neuralgia, chemotherapy-induced neuropathy, trigeminal neuralgia, and other painful neurologic disorders. Several professional societies including the European Federation of Neurological Societies, Canadian Pain Society, and the Special Interest Group on Neuropathic Pain of the IASP have produced evidence-based guidelines for pharmacologic treatments of neuropathic pain, and most of their recommendations are overlapping. Their recommendations for the first- and second-line pharmacologic options are summarized in Table 59.3. Drugs beyond the second-line options arguably have weaker evidence. In general, it is recommended that oral medications be started at low dose, then gradually increased as tolerated, to achieve the lowest dose that offers the most benefit with the least side effects (Table 59.4).

TABLE 59.3 Evidence-Based Guidelines for Pharmacologic Treatments of Neuropathic Pain From Three Groups

	EFNS	CPS	NeuPSIG
First line	**Diabetic neuropathy** Gabapentin Pregabalin TCAs Duloxetine Venlafaxine **Postherpetic neuralgia** Gabapentin Pregabalin TCAs Lidocaine 5% topical **Trigeminal neuralgia** Carbamazepine Oxcarbazepine	Gabapentin Pregabalin TCAs Duloxetine Venlafaxine Carbamazepine (for trigeminal neuralgia)	Gabapentin Pregabalin TCAs Duloxetine Venlafaxine
Second line	**Diabetic neuropathy** Tramadol **Postherpetic neuralgia** Topical Capsaicin Tramadol Other opioids	Tramadol Other opioids Topical lidocaine	Topical lidocaine Topical capsaicin Tramadol

Abbreviations: CPS, Canadian Pain Society; EFNS, European Federation of Neurological Societies; NeuPSIG, Special Interest Group on Neuropathic Pain of the International Association for the Study of Pain; TCAs, tricyclic antidepressants.

Gabapentinoids

It is believed that gabapentinoids exert their pain modulating effect by antagonizing the α2δ subunit of presynaptic DRG calcium channels, which has been shown to be upregulated after nerve injury. Systematic review and meta-analysis of high-quality RCTs have shown both gabapentin and pregabalin significantly reduce pain intensity and also improve function and quality of life, in diabetic neuropathy and postherpetic neuralgia LEVEL 2.[1-5] However, gabapentin was less effective when applied to multietiology neuropathic pain that included conditions such as poststroke, phantom limb, and complex regional pain syndrome. Gabapentinoids are generally well tolerated at low dose and may increase with escalating dose. Common side effects may include drowsiness, mental slowing, erectile dysfunction, and less commonly, peripheral edema as well as myoclonus. It is recommended that starting dose be no more than 300 mg for gabapentin and no more than 75 mg twice a day for pregabalin. Doses are titrated up gradually as tolerated. Doses of 1,800 to 3,600 mg a day for gabapentin and 300 to 600 mg a day for pregabalin may be required for efficacy.

Serotonin-Norepinephrine Reuptake Inhibitors and Tricyclic Antidepressants

Serotonin-norepinephrine reuptake inhibitors (SNRIs) decrease presynaptic uptake of norepinephrine and serotonin, increasing their availability in the synaptic junction. It is thought that these neurotransmitters are mediators of the descending inhibitory systems (ie, from the PAG) that modulate pain transmission between DRG and dorsal horn neurons. Examples of SNRIs include duloxetine and venlafaxine. Meta-analysis of high-quality RCTs concluded that duloxetine was an effective treatment option for diabetic neuropathy pain LEVEL 2.[6] Venlafaxine was also demonstrated to significantly reduce neuropathic pain in RCTs that included diabetic neuropathy, chemotherapy-induced neuropathy, and spinal cord injury LEVEL 2.[7] Duloxetine 60 to 120 mg a day and venlafaxine 75 to 150 mg a day are generally well tolerated, with minor side effects. However, caution is advised when used with concomitant selective serotonin reuptake inhibitor (SSRI) or monoamine oxidase inhibitor to avoid serotonin syndrome.

TABLE 59.4 Medications Used to Treat Neuropathic Pain

Medication	Starting Doses	Maintenance Doses	Data Supporting the Use	Selected Side Effects
Antidepressants				
Duloxetine	20-30 mg every day	60-120 mg/d	PCT—diabetic neuropathy	Diarrhea, nausea, dizziness
Amitriptyline	10-25 mg every night at bedtime	50-150 mg/d	PCT—diabetic neuropathy	Arrhythmia, urinary retention, sexual dysfunction
Nortriptyline	10-25 mg every night at bedtime	50-150 mg/d	RCT—herpetic neuralgia	Less somnolence and orthostatic hypotension than amitriptyline
Venlafaxine	37.5 mg every day	150-375 mg/d	RCT—diabetic neuropathy, chemotherapy-induced neuropathy	Hypertension, sexual dysfunction, nausea
Bupropion SR	150 mg every day	150 mg twice a day	PCT—neuropathic pain	Dry mouth, headache, insomnia, dizziness
Anticonvulsants				
Pregabalin	75 mg twice a day	150-300 mg twice a day	PCT—diabetic neuropathy, postherpetic neuralgia	Somnolence, fatigue, pedal edema, weight gain
Gabapentin	100 mg 3 times a day	300 mg 3 times a day to 1,200 mg 4 times a day	PCT—diabetic neuropathy, postherpetic neuralgia	Somnolence, fatigue, pedal edema
Lamotrigine	25 mg every day	100-250 mg twice a day	PCT—HIV neuropathy, diabetic neuropathy	Stevens-Johnson rash
Oxcarbazepine	75 mg every night at bedtime	300-1,200 mg twice a day	RCT—trigeminal neuralgia	Gastrointestinal ataxia, hyponatremia, rash
Topiramate	15-25 mg every night at bedtime	100-400 mg twice a day	Anecdotal reports—diabetic neuropathy, neuropathic pain	Somnolence, word-finding difficulties, kidney stones
Lacosamide	100 mg every day	400 mg every day	PCT—diabetic neuropathy	Dizziness, nausea
Other Medications				
Mexiletine	150 mg daily	600-1,200 mg daily	Anecdotal, subgroup analysis of PCT	Nausea/vomiting, palpitations, chest pain
Tramadol	25 mg daily	200-400 mg daily	PCT—diabetic neuropathy	Seizures, nausea, headache, constipation, somnolence
CR-oxycodone	10 mg every day	40 mg every day	PCT—diabetic neuropathy	Constipation, somnolence, nausea, dizziness, vomiting
Tapentadol ER	50 mg twice a day	100-250 mg twice a day	PCT—diabetic neuropathy	Constipation, somnolence, dizziness, nausea, vomiting, fatigue
Tizanidine	1 mg daily	4-36 mg daily	Open-label studies in neuropathic pain	Dizziness, drowsiness, fatigue, liver damage
Methadone	5 mg daily	10-20 mg daily	PCT—neuropathic pain	Nausea, dizziness, constipation
Capsaicin 8% patch	1 patch	1 patch every 12 wk	PCT—postherpetic neuralgia, HIV neuropathy	Application site reactions, including increase in pain, nausea
Lidocaine patch 5%	1 patch for 12 h	1-3 patches for 12 h	PCT—postherpetic neuralgia	Application site reactions

Abbreviations: CR, controlled release; ER, extended release; HIV, human immunodeficiency virus; PCT, placebo-controlled trials; RCT, randomized controlled trials; SR, sustained release.

Similarly, tricyclic antidepressants (TCAs) are older generation antidepressants that have reuptake inhibition for norepinephrine, serotonin, and dopamine. They may also promote the pain modulatory effects of the descending inhibitory pathways; however, there is evidence that TCAs may suppress voltage-gated ions channels of dorsal horn neurons as well. Examples of these include amitriptyline and desipramine, which were shown in RCTs to offer significant pain relief, including burning and lancinating pain, that were independent of depression, in diabetic neuropathy and postherpetic neuralgia LEVEL 1.[8-10] Nortriptyline is another TCA that has been shown to be as effective as amitriptyline for pain relief in postherpetic neuralgia but has fewer side effects compared to amitriptyline. Their benefits may not be apparent until 50 to 75 mg a day is reached. However, common side effects of TCAs include somnolence, weight gain, and anticholinergic effects, that is, dry mouth and constipation. Furthermore, there may be increased risk of dysrhythmia, including the prolonged QT syndrome. Therefore, because of their anticholinergic effects, TCAs may not be ideal for elderly patients. Again, caution is advised with concomitant SSRI and monoamine oxidase inhibitor to avoid serotonin syndrome.

Sodium Channel Antagonists

Local anesthetics such as lidocaine exert their analgesic effect by blocking voltage-gated sodium ion channels of the peripheral nerves, impairing the generation, or propagation of action potentials. Topical lidocaine 5% (plaster and patch) has been shown to reduce pain intensity and allodynia in postherpetic neuralgia and other neuropathic pain syndromes LEVEL 1.[11,12] Aside from possible local skin irritations, topical lidocaine has minimal systemic side effects if used as directed and may be preferred for patients with localized areas of neuropathic pain. A 5% patch

may be effective for 12 to 24 hours, although one could use up to three patches a day. However, increased absorption of lidocaine systemically carries some risk of cardiac arrhythmia; thus, use in excess of its daily recommended dose should be avoided.

Oral options of sodium channel antagonists, such as mexiletine, were reported to be efficacious for painful neuropathy in diabetes from early studies. However, systematic review of RCTs involving mexiletine showed that the degree of pain reduction was small, uncertain if clinically meaningful. Not surprisingly, mexiletine has been reported to be beneficial for the pain in various channelopathies such as congenital erythromelalgia, myotonia, and paramyotonia congenita. However, it is a nonselective antagonist of Na_v, thus associated with side effects involving the cardiac and central nervous system, that is, arrhythmia, dizziness, and drowsiness.

There are ongoing efforts to develop therapeutic agents that target the Na_v that are more selectively expressed in the peripheral nervous system.

Antiepileptics

In theory, the anticonvulsive medications carbamazepine and oxcarbazepine, may also exert their therapeutic effect for neuropathic pain by antagonizing sodium channels. Carbamazepine and oxcarbazepine are first-line treatments for trigeminal neuralgia, with oxcarbazepine being better tolerated LEVEL 2.[13,14] Carbamazepine and oxcarbazepine were effective in other neuropathic pain syndromes including in diabetic neuropathy in small RCTs, although other RCTs have reported inconsistent results. An RCT showed that oxcarbazepine was more effective for neuropathic pain with an "irritable nociceptor" phenotype, defined as hypersensitivity with preserved small fiber function determined by quantitative sensory testing, than those of a nonirritative nociceptor phenotype. Starting dose at 100 mg for carbamazepine and 300 mg for oxcarbazepine are reasonable, titrating up for optimal effect. Common side effects may include dizziness and hyponatremia.

Many of the other antiepileptics including lamotrigine, valproic acid, lacosamide, levetiracetam, topiramate, and phenytoin, have had at least some reported efficacy for various neuropathic pain syndromes from RCTs.

Capsaicin

Capsaicin patch 8% was demonstrated to reduce pain intensity in some patients with postherpetic neuralgia, human immunodeficiency virus neuropathy, and diabetic neuropathy in RCTs LEVEL 2.[15,16] Capsaicin activates the vanilloid receptors of the nociceptive DRGs, leading to subsequent depletion of substance P, a nociceptive neurotransmitter. However, until the depletion of substance P is reached, there may be an increase in pain for up to 1 to 2 weeks initially. If this initial increased pain can be tolerated, the subsequent improvement of pain intensity may last up to 12 weeks. Aside from local skin irritation, accidental contact with mucous membranes (ie, eyes) would result in severe irritation, thus application of this medication should be exercised with caution.

Opioids and Other Controlled Substances

The mechanism of action of opioid is complex. Different types of opioid receptors are found throughout the central and peripheral nervous system. The effect of the opioid depends on the type of receptor it activates, and the subsequent G protein coupled intracellular cascades that follow. With regard to neuropathic pain, activation of opioid receptors on nociceptive neurons may lead to decreased calcium influx and increased potassium efflux, which increase the threshold of action potential generation, reducing neuronal excitability. Other effects of opioid receptor activation include anticholinergic effects, sedation, and euphoria. Opioids can be effective for neuropathic pain, for example, oxycodone controlled release, levorphanol, and methadone were found to reduce pain intensity of painful neuropathy in RCTs. However, due to their numerous adverse effects associated with long-term use, potential for addiction, and a recent rise in overdose-related death, it is generally not the ideal option for neuropathic pain. Tramadol is a relatively weaker opioid with some norepinephrine reuptake inhibition activity. Systematically reviewed RCTs showed tramadol to be effective at significantly reducing pain intensity and have therapeutic effects on various aspects of neuropathic pain such as paresthesia, allodynia, and touch-evoked pain LEVEL 1.[17] Still, caution is advised when prescribing any opioid, and close monitoring of any signs of dependence is warranted.

Other Pharmacologic Agents

Considering the role of NMDA receptor activation in the development of sensitization in neuropathic pain, there has been some interest in utilizing drugs with NMDA receptor antagonist activity, such as dextromethorphan, ketamine, and memantine, for chronic pain. However, their benefit for neuropathic pain is uncertain.

In addition to SNRI and TCA, SSRIs have been thought to offer benefit for neuropathic pain. For example, escitalopram was shown to be effective in painful polyneuropathy in an RCT. However, evidence supporting the use of SSRI for neuropathic pain is relatively limited.

Bupropion is an antidepressant that has predominantly dopamine reuptake inhibition as well as some norepinephrine reuptake inhibition and NMDA antagonistic effect. One RCT showed bupropion sustained release reduced pain intensity and improve quality of life in patients with neuropathic pain due to a variety of etiologies that include diabetic neuropathy, phantom limb pain, radiculopathy, etc.

Systematic review of cannabinoids (including herbal cannabis, plant-derived or synthetic tetrahydrocannabinol [THC], oromucosal spray) found low to moderate quality evidence of reducing neuropathic pain intensity and sleep problems. However, the benefit may be outweighed by side effects that included dizziness, sleepiness, and confusion.

Alpha-lipoic acid is a coenzyme in the Krebs cycle, it has antioxidant effect and was shown to reduce diabetic microvascular complications in animal models. Intravenous alpha-lipoic acid has been shown to reduce diabetic neuropathy pain in short-term clinical trials. However, the benefit of its oral analogue, as well as its benefit for neuropathic pain from other disorders, are unclear.

Cognitive Behavioral and Physical Therapy

Cognitive behavioral therapy (CBT) and physical therapy are often used in the management of chronic pain. Results from RCTs evaluating the effect of psychological therapy on neuropathic pain have been conflicting, and the quality of some of these trials have been deemed suboptimal. Thus, the effect of CBT on neuropathic pain is inconclusive. Also, CBT methods may vary among different therapists. Despite the lack of rigorous evidence for efficacy in painful neuropathy, CBT is relatively safe and therefore may be a treatment option. Regarding physical therapy, there is insufficient evidence to conclude the effect of exercise on the functional outcome of patients with neuropathy pain (except

some improvement of muscle strength). On the other hand, for chronic pain in general, some RCTs showed exercise may reduce the severity of chronic pain, although these findings have not been consistent in other studies. Some of the inconsistency may stem from the variety of physical activities employed in different studies. However, considering the overall health benefit of regular exercise, its low risk of significant harm (especially with proper physical therapy guidance), and that it may offer benefit in some patients, physical therapy, and exercise are often recommended in conjunction with pharmacologic treatment for chronic pain.

Procedural Interventions

There is ongoing evaluation of various procedural interventions for the treatment of neuropathic pain. These include botulinum toxin A, transcranial cortical stimulation, as well as nerve root and peripheral nerve stimulation, with either inconclusive findings or weak evidence so far.

OUTCOME

Despite a wide variety of pharmacologic and nonpharmacologic treatment options for neuropathic pain, the result is often unsatisfactory for the patient. In a recent long-term prospective observational study for neuropathic pain (including central and peripheral causes), using the Canadian Pain Society treatment guidelines, only 32.4% of the patients achieved significant pain reduction (defined as 30% or greater pain reduction at 12 months) from baseline. It also showed central neuropathic pain was less likely to respond than pain of peripheral origin. Indeed, there are challenges to the pursuit of more effective treatments. Eligibility criteria for neuropathic pain trials are often based on etiologic categories such as diabetic neuropathy or trigeminal neuralgia. Individuals within the same etiologic category may have pain that arises from distinct mechanisms. This mechanistic heterogeneity may diminish our ability to measure benefits in randomized trials and to optimize treatment in clinical practice. Some have advocated a mechanism-based approach to pain diagnosis, emphasizing identifying the underlying neuroplastic changes (ie, those that lead to sensitization) that promote and perpetuate maladaptive pain. There are ongoing attempts to develop such methods. At least in theory, being able to identify and tailor treatments to the mechanisms that give rise to neuropathic pain may yield more satisfactory clinical results. In addition, the subjective pain scales and quality of life assessment tools that are used as outcome measures may not optimally measure the burden of illness or benefits of treatment. Identifying mechanism-based subgroups of patients with neuropathic pain, treatments that are most effect in these subgroups, and patient-centered measures offers hope for improving outcomes.

Classification of Seizures and Epilepsy 60

Shraddha Srinivasan and Carl W. Bazil

KEY POINTS

1. Although seizures are the cardinal manifestation of epilepsy, not all seizures imply epilepsy.
2. Antiseizure prophylaxis is strongly recommended for a single unprovoked seizure accompanied by a significant magnetic resonance imaging abnormality and/or epileptiform EEG features.
3. Epilepsy syndrome identification aids in determining the cause of the epilepsy, its prognosis, and selection of appropriate antiseizure medication.
4. Frontal lobe seizures can involve bizarre hypermotor behaviors, vocalizations, and gesticulations that can be misdiagnosed as psychogenic nonepileptic seizures.
5. The new International League Against Epilepsy classification system recognizes two new categories: "combined generalized and focal epilepsy" and "unknown epilepsy."

INTRODUCTION

An epileptic seizure is the result of a temporary physiologic dysfunction of the brain caused by an abnormal, self-limited, and hypersynchronous electrical discharge of cortical neurons. There are many different kinds of seizures, each with characteristic behavioral changes and electrophysiologic disturbances that can usually be detected with scalp electroencephalography (EEG) recordings. The particular manifestations of any single seizure depend on several factors: whether most or only a part of the cerebral cortex is involved at the beginning, the functions of the cortical areas where the seizure originates, the subsequent pattern of spread of the electrical ictal discharge within the brain, and the extent to which subcortical and brainstem structures are engaged.

Although seizures are the cardinal manifestation of epilepsy, not all seizures imply epilepsy. Acute symptomatic seizures refer to seizures that occur only during the course of an acute medical or neurologic illness such as metabolic disarray or drug intoxication; they usually do not persist after the underlying disorder has resolved. Some people, for no discoverable reason, have a single unprovoked seizure. These seizures are not consistent with epilepsy.

Epilepsy is a chronic disorder, or group of chronic disorders, in which the indispensable feature is recurrence of seizures that are typically unprovoked and usually unpredictable. Each distinct form of epilepsy has its own natural history and response to treatment. This diversity presumably reflects the fact that epilepsy can arise from a variety of underlying conditions and pathophysiologic mechanisms.

The operational definition of epilepsy proposed by the International League Against Epilepsy (ILAE) is that it is a chronic disease of the brain defined by any of the following conditions:

1. At least two unprovoked (or reflex) seizures occurring more than 24 hours apart
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years
3. Diagnosis of an epilepsy syndrome (see "Epilepsy Syndromes" ahead)

Reflex epilepsy is the condition of provoked reflex seizures (eg, to photic stimuli) that are recurrent. They can be focal, such as musicogenic epilepsy with temporal lobe seizures and visual seizures of photosensitive occipital lobe epilepsy, or generalized in onset. Patients with reflex epilepsy can have spontaneous seizures too, but very frequently have a precipitating factor for their seizures.

Each distinct form of epilepsy has its own natural history and response to treatment. This diversity presumably reflects the fact that epilepsy can arise from a variety of underlying conditions and pathophysiologic mechanisms, although most cases are classified as idiopathic (of presumed genetic origin).

EPIDEMIOLOGY

More than 50 million people worldwide have epilepsy, making it one of the most common neurologic diseases globally. An estimated proportion of the general population with active epilepsy (ie, continuing seizures or with the need for treatment) at a given time is between 4 and 10 per 1,000 people (https://www.who.int/news-room/fact-sheets/detail/epilepsy).

The annual incidence rates for epilepsy in the United States is estimated at 150,000 or 48 for every 100,000 people. Based on 1990 census figures, age-adjusted annual incidence rates for epilepsy range from 31 to 57 per 100,000 in the United States (Fig. 60.1). Incidence rates are highest among young children and the elderly.

FIGURE 60.1 Age-specific incidence of epilepsy in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34[3]:453-468.)

Focal impaired awareness seizures (previously called *complex partial seizures*) are the most common seizure type among newly diagnosed cases, but age-related variability occurs in the proportions of different seizure types (Fig. 60.2). The cause of epilepsy also varies somewhat with age. Despite advances in diagnostic capabilities, however, the "unknown" etiologic category remains larger than any other for all age groups (Fig. 60.3). Cerebrovascular disease, associated developmental neurologic disorders (eg, cerebral palsy and mental retardation), and head trauma are the other most commonly identified causes.

Although defined genetic disorders account for only about 1% of epilepsy cases, heritable factors are important. Monozygotic twins have a much higher concordance rate for epilepsy than do dizygotic twins. By age 25 years, nearly 9% of children of mothers with epilepsy and 2.4% of children of affected fathers develop epilepsy. The reason for an increased risk of seizures in children of women with epilepsy is not known.

Some forms of epilepsy are more heritable than others. For example, children of parents with absence seizures have a higher risk of developing epilepsy (9%) than do offspring of parents with other types of generalized seizures or focal seizures (5%). As a general rule though, even offspring born to a high-risk parent have a 90% or greater chance of being unaffected by epilepsy.

Many persons who experience a first unprovoked seizure never have a second. By definition, these people do not have epilepsy and generally do not require long-term drug treatment. Unfortunately, our ability to identify such individuals with accuracy is imperfect. Treatment decisions must be based on epidemiologic and individual considerations. Some seizure types, such as absence and myoclonic, are virtually always recurrent by the time the patient is seen by a physician. On the other hand, patients with convulsive seizures may seek medical attention after a first occurrence because of the dramatic nature of the episode. Prospective studies of recurrence after a first seizure indicate a 2-year recurrence risk of about 40%, which is similar in children and adults. The risk is lowest in people with an idiopathic generalized first seizure and normal EEG (about 24%), higher with idiopathic generalized seizures and an abnormal EEG (about 48%), and highest with symptomatic (ie, known preceding brain injury or neurologic syndrome) seizures and an abnormal EEG (about 65%). Epileptiform, but not nonepileptiform, EEG abnormalities impart a greater risk for recurrence. Additionally, if the first seizure is a focal seizure or a nocturnal seizure, the relative risk of recurrence is also increased. The risk for further recurrence after a second unprovoked seizure is greater than 80%; a second unprovoked seizure is, therefore, a reliable marker of epilepsy.

The American Academy of Neurology and the American Epilepsy Society evidence-based guidelines for the counseling and management of a first unprovoked seizure are summarized in the following text LEVEL 1.[1]

FIGURE 60.2 Proportion of seizure types in newly diagnosed cases of epilepsy in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34[3]:453-468.)

FIGURE 60.3 Etiology of epilepsy in all cases of newly diagnosed seizures in Rochester, Minnesota, 1935-1984. (From Hauser WA, Annegers JF, Kurland LT. Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia*. 1993;34[3]:453-468.)

Adults presenting with an unprovoked first seizure should be informed that the chance for a recurrent seizure is greatest within the first 2 years after a first seizure (21%-45%). Patients should be advised that clinical factors associated with an increased risk for seizure recurrence include a prior brain insult such as a stroke or trauma, an EEG with epileptiform abnormalities, a significant brain imaging abnormality, or a nocturnal seizure. Clinicians should advise patients that although immediate antiseizure medication therapy, as compared with delay of treatment pending a second seizure, is likely to reduce the risk for a seizure recurrence in the 2 years subsequent to a first seizure, it may not improve quality of life. Patients should be advised that over the longer term (>3 y), immediate antiepileptic drug (AED) treatment is unlikely to improve the prognosis for sustained seizure remission. Additionally, their risk for medication-related adverse effects ranges from 7% to 31% and that these adverse effects are predominantly mild and reversible.

About 4% of persons living to age 74 years have at least one unprovoked seizure. When provoked seizures (ie, febrile seizures or those related to an acute illness) are included, the likelihood of experiencing a seizure by age 74 years increases to at least 9%. The risk of developing epilepsy is about 3% by age 74 years.

Of persons with epilepsy, 60% to 70% achieve remission of seizures with AED therapy. Factors that favor remission include an idiopathic form of epilepsy, normal findings on neurologic examination, and onset in early to middle childhood (except neonatal seizures). Unfavorable prognostic factors include focal seizures, an abnormal EEG, an abnormal neurologic examination, and associated mental retardation or cerebral palsy (Table 60.1). Those who fail to achieve remission have drug-resistant epilepsy and may be candidates for alternative therapies, including surgery, devices or dietary therapies. Drug-resistant epilepsy is defined by the ILAE as "failure of adequate trials of two tolerated and appropriately used antiepileptic drugs to achieve sustained seizure freedom."

Mortality is increased in persons with epilepsy, but the risk is incurred mainly by symptomatic cases in which higher death rates are related primarily to the underlying disease rather than to epilepsy. Accidental deaths, especially drowning, are not uncommon, however, in all patients with epilepsy. Sudden unexplained death is nearly 25 times more common in patients with epilepsy than in the general population; estimates of incidence rates range from 1 in 500 to 1 in 2,000 per year in adults and 1 in 4,500 per year in children with epilepsy LEVEL 2.[2] Severe epilepsy, uncontrolled generalized convulsions, especially nocturnal, and need for multiple antiseizure medications are risk factors.

TABLE 60.1 Predictors of Intractable Epilepsy

Very young at onset (<2 y)
Frequent generalized seizures
Failure to achieve control readily
Evidence of brain damage
A specific cause of the seizures
Severe EEG abnormality
Low IQ
Presence of atonic seizures or atypical absence seizures

Abbreviation: EEG, electroencephalogram.

Gene Mutations in Epilepsy

Twin and population studies have supported a genetic contribution in both focal and generalized epilepsies. The concordance rate for monozygotic twins with idiopathic generalized epilepsy is well over 75%. Epilepsies resulting from pathogenic variants in single genes are rare, however, and include familial epilepsies with Mendelian inheritance and sporadic epilepsies associated with neurodevelopmental disability. The last 25 years have identified a number of genes responsible for these rare epilepsies. Moreover, it is increasingly recognized that focal epilepsies with (and even without) cortical malformations may be associated with somatic mosaicism, resulting from postzygotic mutations arising during development. The relationship between genotype and phenotype is complex with genetic heterogeneity (ie, one syndrome having multiple genetic causes) and phenotypic heterogeneity (ie, one gene manifesting with different phenotypes). Genetic testing includes cytogenetic approaches to evaluate copy number variation as well as sequencing approaches to investigate more discrete changes. The benefits of testing include termination of the diagnostic odyssey and in a growing number of situations, precision medicine approaches targeting the underlying pathology; for example, ketogenic diet for Glut1 deficiency syndrome caused by pathogenic variants in *SLC2A1* and pyridoxine (vitamin B_6) for pyridoxine-dependent epilepsy, a recessive condition caused by mutations in the *ALDH7A1* gene.

Examples of causative genes that have been identified in epilepsies with Mendelian inheritance include *KCNQ2* and *KCNQ3*, voltage-gated potassium channel genes associated with benign familial neonatal epilepsy; *CHRNA4* and *CHRNB2*, nicotinic acetylcholine receptor subunits associated with autosomal dominant nocturnal frontal lobe epilepsy; *SCN1A*, a voltage-gated sodium channel associated with genetic epilepsy with febrile seizures; *LGI1*, leucine-rich glioma inactivated 1, associated with autosomal dominant epilepsy with auditory features; and *DEPDC5*, associated with familial focal epilepsy with variable foci. For further details on genetics of epileptic disorders, refer to Chapter 143.

CLASSIFICATIONS OF SEIZURES AND EPILEPSY

Accurate classification of seizures and epilepsy is essential for understanding epileptic phenomena, developing a rational plan of investigation, making decisions about when and for how long to treat, choosing the appropriate AED, and conducting scientific investigations that require delineation of clinical and EEG phenotypes.

Classification of Seizures

The initial events of a seizure, described by either the patient or an observer, are usually the most reliable clinical indication to determine whether a seizure begins focally or is generalized from the moment of onset. Sometimes, however, a focal signature is lacking for several possible reasons:

1. The patient may be amnesic after the seizure, with no memory of early events.
2. Consciousness may be impaired so quickly or the seizure may generalize so rapidly that early distinguishing features are blurred or lost.
3. The seizure may originate in a brain region that is not associated with an obvious behavioral function. Thus, the seizure becomes clinically evident only when the discharge spreads beyond the ictal-onset zone or becomes generalized.

Additionally, generalized onset seizures can have focal features such as versive head turn; asymmetry or asynchrony in the clonic phase of a generalized tonic-clonic seizure; an episode of typical absence preceding a generalized tonic-clonic seizure, which can be misinterpreted as an aura or a complex partial seizure; as well as focal EEG abnormalities such as only fragments of a generalized spike wave.

The prior and current ILAE classification systems attempt to group seizures according to onset and clinical presentation and to group epilepsies according to seizure type, age of onset, probability of remission, EEG findings, radiologic findings, and genetics. Beginning in 2010, the term *focal seizure* officially replaced *partial seizure*. The new classification addresses some limitations of the 1981 seizure classification. Some seizures can have either focal or generalized onset such as tonic-clonic seizures, an unknown onset of a seizure, that makes it unclassifiable and difficult to place within the 1981 system; terms such as *complex partial* and *simple partial seizures* are difficult to understand and explain; and some seizure types such as myoclonic-atonic seizures and eyelid myoclonia were not included in the 1981 classification.

Focal Seizures

Focal seizures are further classified according to (1) the level of awareness, (2) the first and most prominent motor or nonmotor feature of the seizure, and (3) whether the focal seizure evolves to a bilateral tonic-clonic seizure. The term *secondary generalized tonic-clonic seizure* is now replaced by *focal to bilateral tonic-clonic seizure*. For instance, if a patient presents with an aura of deja vu followed by losing awareness and witnessed lip smacking, the seizure type is classified as focal impaired awareness seizure with automatisms. If the seizure involves tonic-clonic activity with no focal signature witnessed or reported by the patient, such as an aura or a focal clonic jerk, the seizure would be classified as unknown onset seizure with bilateral tonic-clonic activity. As previously mentioned, the term simple partial seizure is now replaced by focal aware seizure, and the term complex partial seizure is replaced by focal impaired awareness seizure.

Focal aware seizures result when the ictal discharge occurs in a limited and often circumscribed area of cortex. Almost any symptom or phenomenon can be the subjective (aura) or observable manifestation of a focal aware seizure, varying from elementary motor (jacksonian seizures, adversive seizures) and unilateral sensory disturbance to complex emotional, psychoillusory, hallucinatory, or dysmnesic phenomena. Especially common auras include an epigastric rising sensation, fear, a feeling of unreality or detachment, déjà vu (a familiar feeling) and jamais vu (feeling of unfamiliarity) experiences, and olfactory hallucinations. Patients can interact normally with the environment during focal aware seizures except for limitations imposed by the seizure on specific localized brain functions, such as aphasia during a dominant temporal lobe seizure, which could be confused for lack of awareness due to the patient's inability to speak.

Motor manifestations include automatisms; epileptic spasms; and atonic, clonic, hyperkinetic, myoclonic, or tonic movements. Automatisms are coordinated, purposeless, repetitive motor activities that may appear normal in other circumstances. Examples include oral automatisms such as lip smacking and manual automatisms including repetitive hand movements. Of note, automatisms can also be seen in absence seizures, which are discussed later.

Focal impaired awareness seizures, on the other hand, are defined by impaired consciousness and imply further spread of the seizure discharge at least to basal forebrain and limbic areas. In addition to impaired awareness, patients with these seizures usually exhibit automatisms, such as lip smacking, repeated swallowing, clumsy perseveration of an ongoing motor task, or some other complex motor activity that is purposeless. Postictally, patients are confused and disoriented for several minutes, and determining the transition from ictal to postictal state may be difficult without simultaneous EEG recording. Of focal impaired awareness seizures, 70% to 80% arise from the temporal lobe; foci in the frontal and occipital lobes account for most of the remainder.

Generalized Seizures

The new classification includes a few additional types of seizures in this category. The presence or absence of predominant motor activity further classifies these seizures (**Fig. 60.4**). Predominantly, motor seizure types are further classified as tonic, clonic, tonic-clonic, myoclonic, atonic, myoclonic-tonic-clonic, myoclonic-atonic, and epileptic spasms.

Generalized tonic-clonic seizures (▶ **Video 60.1**) are characterized by abrupt loss of consciousness with bilateral tonic extension of the trunk and limbs (*tonic phase*), often accompanied by a loud vocalization as air is forcedly expelled across contracted vocal cords (*epileptic cry*), followed by synchronous muscle jerking (*clonic phase*). Postictally, patients are briefly unarousable and then lethargic and confused, often preferring to sleep. Many patients report inconsistent nonspecific premonitory symptoms (*epileptic prodrome*) for minutes to a few hours before a generalized tonic-clonic seizure. Common symptoms include ill-defined anxiety, irritability, decreased concentration, and headache or other uncomfortable feelings; these are not auras. *Myoclonic* seizures are characterized by rapid brief muscle jerks that can occur bilaterally, synchronously or asynchronously, or unilaterally. Myoclonic jerks range from isolated small movements of face, arm, or leg muscles to massive bilateral jerks simultaneously affecting the head, limbs, and trunk.

FIGURE 60.4 International League Against Epilepsy classification of seizure types. (From Fisher RS, Cross JH, D'Souza C, et al. Instruction manual for the ILAE 2017 operational classification of seizure types. *Epilepsia*. 2017;58[4]: 531-542. doi:10.1111/epi.13671.)

Atonic seizures (▷ Video 60.2), also called *drop attacks*, are characterized by sudden loss of muscle tone, which may be fragmentary (eg, head drop) or generalized, resulting in a fall. The term *astatic seizure* is now no longer in use.

Myoclonic-atonic seizures are atonic seizures that are preceded by a brief myoclonic seizure, resulting in an acceleratory force added to the fall, thereby contributing to the high rate of self-injury with this type of seizure. These seizures are a common characteristic of Doose syndrome.

Epileptic spasms are also brief and typically occur in clusters with flexion at the trunk and flexion or extension of the limbs. As with focal epileptic spasms, an EEG may be needed to distinguish whether the seizure is generalized.

Absence seizures, where the motor component is not predominant, are momentary lapses in awareness that are accompanied by motionless staring and arrest of any ongoing activity. Absence seizures begin and end abruptly; they occur without warning or postictal period. Mild myoclonic jerks of the eyelid or facial muscles, variable loss of muscle tone, and automatisms may accompany longer attacks. When the beginning and end of the seizure are less distinct, or if tonic and autonomic components are included, this is more likely an atypical absence seizure, which has an EEG correlate of slow spike and wave (less than 3 Hz frequency). Atypical absences are seen most often in children with epilepsy who are developmentally delayed or in epileptic encephalopathies, such as the Lennox-Gastaut syndrome (described later in this chapter).

A triad of eyelid myoclonia (eyelid fluttering) with and without absence seizures, eye closure–induced seizures and EEG paroxysms, and photosensitivity is characteristic of Jeavons syndrome, a type of idiopathic generalized epilepsy.

Unknown Onset Seizures

As described earlier, when a clear focal signature is not obtained by history or testing, seizures are classified under this category. They can be further classified as motor (eg, epileptic spasm, tonic-clonic) or nonmotor (eg, behavior arrest) in type.

Classification of Epilepsies

Similar to seizure classification, the epilepsies are classified as generalized or focal.

The new classification system additionally recognizes two new categories: *combined generalized and focal epilepsy* and *unknown epilepsy*. Patients with both focal and generalized onset seizures have electrophysiologic data that may reveal both focal and generalized electrographic findings. The epilepsy type here would conform to a *combined generalized and focal epilepsy*. Some examples include Dravet syndrome and Lennox-Gastaut syndrome.

If the patient's epilepsy is undetermined, it is classified under *unknown epilepsy*. Typically, EEGs or other supporting studies such as magnetic resonance imaging (MRI) and family history are either unavailable or inconclusive (Fig. 60.5).

FIGURE 60.5 Framework for classification of the epilepsies. *Denotes onset of seizure. (From Scheffer IE, Berkovic S, Capovilla G, et al. ILAE Classification of the Epilepsies: position paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58[4]:512-521. doi:10.1111/epi.13709.)

Generalized Epilepsy

Patients with generalized epilepsy have one or more of the generalized seizure types, and their EEGs typically display generalized spike-wave activity. For individuals who have generalized seizure types and a normal EEG, other data are needed to determine whether the epilepsy is generalized. Having myoclonic jerks supports the diagnosis of a generalized epilepsy type.

Case 1. A 17-year-old girl presented for evaluation after experiencing a single generalized tonic-clonic seizure. Her history revealed that for the past 3 years, she would often have brief intermittent jerks of her arms or legs, typically in the morning. The larger jerks would result in her legs giving way and she would suddenly drop to the ground and feel confused for a split second. She took no medications and had no substance abuse history. Brain MRI was normal, and EEG revealed generalized spike-wave discharges (Fig. 60.6). Despite presenting with a single generalized seizure with no focal features, her history of morning myoclonus and EEG findings indicated that she may have an idiopathic generalized epilepsy syndrome. These findings indicated an at least 60% risk of a second unprovoked seizure within the next 10 years. She was diagnosed with juvenile myoclonic epilepsy (JME) and was initiated on levetiracetam.

Focal Epilepsy

Clinically, patients with one or more focal seizure types have focal epilepsy. Seizures in these epilepsies may arise from one or more than one focus. Although not always present, EEG findings such as focal slowing or focal epileptiform discharges support the diagnosis of focal epilepsy. Concordant focal MRI findings are also supportive.

FIGURE 60.6 Electroencephalography in longitudinal bipolar montage demonstrating frontally predominant generalized 3- to 4-Hz epileptiform discharges.

FIGURE 60.7 Brain magnetic resonance imaging coronal fluid-attenuated inversion recovery (FLAIR) and T2-weighted images demonstrating a smaller right hippocampus with increased FLAIR signal.

Temporal Lobe Epilepsy

Case 2. A 27-year-old woman presented with focal seizures with an aura of abdominal discomfort, and a cold sensation that would come over her followed by observed lip smacking and repetitive right hand movements, as well as dystonic posturing of her left hand. She had a prolonged febrile convulsion at age 20 months. Her brain MRI (Fig. 60.7) showed increased fluid-attenuated inversion recovery signal and atrophy of the right hippocampus consistent with mesial temporal sclerosis. The EEG showed epileptiform discharges and focal slowing in the right temporal region (Fig. 60.8). Her epilepsy would be classified as a focal (right temporal lobe) epilepsy, and the seizure type would be focal impaired awareness seizure with automatisms. In this scenario, antiseizure medication should be initiated, and if the seizures continue to occur despite adequate trials of two antiseizure medications, she should be referred to an epilepsy center for an epilepsy surgery work up.

Temporal lobe epilepsy is the most common epilepsy seen in adults. In most cases, the epileptogenic region involves mesial temporal lobe structures, especially the hippocampus,

FIGURE 60.8 Electroencephalography in longitudinal bipolar montage demonstrating right anterior temporal epileptiform discharges.

amygdala, and parahippocampal gyrus. Seizures usually begin in late childhood or adolescence, and a history of febrile seizures is common. Virtually all patients have focal impaired awareness seizures, some of which evolve to bilateral tonic-clonic activity. Auras are frequent; visceral sensations are particularly common. Other typical behavioral features include a motionless stare, loss of awareness that may be gradual, and oral-alimentary automatisms, such as lip smacking. Ipsilateral manual automatisms are also common (▶ Video 60.3). A variable but often prolonged period of postictal confusion is the rule. Interictal EEGs show focal temporal slowing and epileptiform sharp waves or spikes over the anterior temporal region. The AEDs are usually successful in suppressing secondarily generalized seizures, but many patients continue to have less severe attacks. When seizures persist, workup for surgical treatment should be undertaken as up to 80% of selected patients will achieve complete seizure freedom (see following chapter).

Frontal Lobe Epilepsy

The particular pattern of the many types of frontal lobe seizures depends on the specific location where the seizure discharge originates and on the pathways subsequently involved in propagation. Despite this variability, the following features, when taken together, suggest frontal lobe epilepsy:

1. Brief seizures that begin and end abruptly with little, if any, postictal period
2. A tendency for seizures to cluster and to occur at night
3. Prominent, but often bizarre, motor manifestations, such as asynchronous thrashing or flailing of arms and legs; pedaling leg movements; pelvic thrusting; and loud, sometimes obscene, vocalizations, all of which may suggest psychogenic seizures (▶ Video 60.4)
4. Minimal abnormality on scalp EEG recordings
5. A history of status epilepticus

Epilepsy Syndromes

The epilepsy syndromes are a new addition to the current classification system, comprising a cluster of features involving seizure types, age of onset, natural history, prognosis, etiologies, EEG patterns, genetics, a predictable response to treatment, comorbidities such as intellectual impairment, psychiatric dysfunction, and, at times, imaging features. The identification of an epilepsy syndrome is useful as it provides information on which underlying etiologies should be considered and which antiseizure medication(s) might be most useful. Several epilepsy syndromes demonstrate seizure aggravation with particular antiseizure medications, which can be avoided through appropriate early diagnosis of the epilepsy syndrome.

The epileptic encephalopathies and self-limited neonatal and childhood epilepsy syndromes will be described in detail in Chapter 143.

Idiopathic Generalized Epilepsy Syndromes

These syndromes include childhood absence epilepsy, juvenile absence epilepsy, JME, and generalized tonic-clonic seizures alone (previously referred to as generalized tonic-clonic seizures upon awakening). The genetics of this syndrome can be inherited or acquired de novo. The EEGs in this epilepsy syndrome reveal generalized spike waves superimposed on a typically normal background.

Childhood Absence Epilepsy

Has an onset that is usually between 4 and 12 years of age, with remission usually in adolescence. Patients present with absence seizures and rare generalized tonic-clonic seizures. The EEG activity during an absence seizure is characterized by stereotyped, bilateral, 3-Hz spike-wave discharges. Generalized tonic-clonic seizures also occur in 30% to 50% of cases. Most children are intellectually and neurologically intact. Ethosuximide and valproate are equally effective in treating absence seizures, but valproate or lamotrigine are preferable if generalized tonic-clonic seizures coexist. Topiramate, levetiracetam, and zonisamide may also be effective in generalized onset seizures.

Juvenile Absence Epilepsy

Has onset in adolescence and early adulthood, with peak onset between 10 and 13 years of age. Seizure types include early-onset generalized tonic-clonic seizures, absence, and myoclonic seizures. This syndrome is not self-limiting.

Juvenile Myoclonic Epilepsy

The JME most often begins in otherwise healthy individuals between the ages of 8 years and mid-20s. The fully developed syndrome comprises morning myoclonic jerks, generalized tonic-clonic seizures that occur just after waking, normal intelligence, a family history of similar seizures, and an EEG that shows generalized spikes, 4- to 6-Hz spike waves, and multiple spike (polyspike) discharges. The myoclonic jerks vary in intensity from bilateral massive spasms and falls to minor isolated muscle jerks that many patients consider nothing more than "morning clumsiness." Absence seizures are rare. Most patients require lifelong antiseizure medication. Linkage studies have produced conflicting results with different groups reporting susceptibility loci on chromosomes 6p, 5q, and 15q. A mutation in the α_1 subunit of the γ-aminobutyric acid A receptor has been found in a large French Canadian family with JME but not in individuals with the common sporadic form of JME. Valproate, lamotrigine, zonisamide, levetiracetam, and topiramate can be equally effective in many patients, although lamotrigine sometimes exacerbates myoclonus.

Selected Focal Epilepsy Syndromes

Autosomal dominant epilepsy with auditory features is a focal epilepsy syndrome characterized by auditory symptoms with or without receptive aphasia as prominent ictal features. Auditory symptoms are simple sounds such as humming, buzzing, or ringing, and less commonly, volume changes or complex sounds such as specific songs or voices can occur. Most patients have focal to bilateral tonic-clonic seizures. Mutations in the *LGI1* have been identified in about 50% families with autosomal dominant epilepsy with auditory features.

Frontal lobe epilepsy occurs in some families as an autosomal dominant syndrome referred to as autosomal dominant nocturnal frontal lobe epilepsy. In these patients, seizures usually occur in clusters during sleep; they are often stereotyped and brief and vary from simple arousals to dramatic bizarre hyperkinetic movements. Most patients respond well to medication, and seizures do become milder and less frequent with advancing age. Molecular genetic testing reveals a heterozygous pathogenic variant in *CHRNA4*, *CHRNB2*, *CHRNA2*, *KCNT1*, *DEPDC5*, or *CRH*.

Self-limited Focal Epilepsy Syndromes of Childhood

Several self-limited focal epilepsies occur in children, of which the most common is the syndrome associated with central midtemporal spikes on EEG. This form of idiopathic focal epilepsy, known as *benign epilepsy with centrotemporal spikes*, also known as benign rolandic epilepsy, accounts for about 15% of all pediatric seizure disorders. This syndrome presents between 4 and 13 years of age with predominantly nocturnal focal motor seizures with preserved consciousness. There are frequent hemifacial twitching episodes; drooling; paresthesias of the tongue, lips, inner cheeks, and face; or speech arrest with or without bilateral tonic-clonic activity.

The interictal EEG abnormality is distinctive and shows stereotyped diphasic or triphasic sharp waves over the central midtemporal (rolandic) regions that are sleep potentiated. Discharges may be unilateral or bilateral. They increase in abundance during sleep and, when unilateral, switch from side to side on successive EEGs. In about 30% of cases, generalized spike-wave activity also occurs. The EEG pattern is inherited as an autosomal dominant trait with age-dependent penetrance. The inheritance pattern of the seizures, although clearly familial, is probably multifactorial and less well understood. More than half the children who show the characteristic EEG abnormality never have clinical attacks. Linkage has been reported in some families to chromosome 15q14.

The prognosis is usually good; however, neuropsychological deficits including linguistic, cognitive, and behavioral impairment have been described in some studies particularly when the seizures are more severe, cluster, and accompanied by tonic-clonic activity. The term *self-limited* is probably more accurate than *benign* for this reason. Seizures disappear by mid to late adolescence in all cases. Treatment is indicated when there is a high seizure burden disrupting sleep or frequent tonic-clonic seizures. Because seizures are easily controlled and self-limited, drugs with the fewest adverse effects, such as carbamazepine, oxcarbazepine, or gabapentin, should be used. Low doses, often producing subtherapeutic blood concentrations, are generally effective. Polytherapy should be avoided.

Panayiotopoulos syndrome is characterized by seizures in childhood that are often prolonged with predominantly autonomic symptoms of ictal nausea/retching/vomiting. These seizures can be mistaken for acute gastroenteritis. Ictal pallor, incontinence of urine, and hypersalivation are also noted at times; cardiac asystole is rare. Seizures are often prolonged and can evolve to clonic or hemiclonic activity. In the majority of children, the onset of seizures is between 3 and 6 years of age. Twenty-five percent of children will have a single seizure (which may be autonomic status epilepticus), and 50% may have six seizures or less. Seizures usually resolve by ages 11 to 13 years. Birth and developmental history are typically normal, as is the neurologic examination. The EEG characteristic is occipital or at times multifocal spikes with a normal background. Treatment with an antiseizure medication is often not necessary but can be considered in the setting of very frequent seizures.

Gastaut-type idiopathic occipital epilepsy of childhood, another self-limited benign focal epilepsy syndrome, is characterized by elementary visual hallucinations, typically multicolored and circular, appearing in the periphery of a hemifield, which may be flashing, may move across the visual field, or remain static. They are usually stereotyped. Ictal blindness and more complex visual hallucinations occur less commonly. Evolution to hemiclonic or bilateral tonic-clonic seizures is known to occur. The EEG is characterized by occipital paroxysms that are typically bilateral and synchronous and induced by eye closure (eliminating visual fixation). Some patients can have reflex photosensitive occipital lobe seizures and photoparoxysmal responses on EEG. Prognosis is not as predictable as in benign epilepsy with centrotemporal spikes and Panayiotopoulos syndrome. Children with this epilepsy often suffer from very frequent seizures, and therefore, the management typically includes an antiseizure medication. Nevertheless, within 2 to 4 years of onset, about 50% to 60% of children achieve remission.

Lennox-Gastaut Syndrome (A Type of Combined Focal and Generalized Epilepsy Syndrome)

This syndrome would be classified under combined focal and generalized epilepsy syndromes. The term *Lennox-Gastaut syndrome* is applied to a heterogeneous group of childhood epileptic encephalopathies that are characterized by mental retardation, uncontrolled seizures, and a distinctive EEG pattern. The syndrome is not a pathologic entity because clinical and EEG manifestations result from brain malformations, perinatal asphyxia, severe head injury, central nervous system infection, or, rarely, a progressive degenerative or metabolic syndrome. A presumptive cause can be identified in 65% to 70% of affected children. Seizures usually begin before age 4 years, and about 25% of children have a history of infantile spasms. No treatment is consistently effective, and 80% of children continue to have seizures as adults. Best results are generally obtained with broad-spectrum antiseizure medications, such as valproate, clobazam, lamotrigine, topiramate, or zonisamide. Rufinamide may be particularly effective for atonic seizures associated with this syndrome. Despite the higher incidence of severe side effects, felbamate is often effective when these other agents do not result in optimal seizure control. Refractory cases may be considered for vagus nerve stimulation or anterior corpus callosotomy. Both of these are palliative procedures, and complete seizure control is rare.

Infantile Spasms (West Syndrome)

The term *infantile spasms* denotes a unique age-specific form of generalized or focal epilepsy that may be either idiopathic or symptomatic. When all clinical data are considered, including results of imaging studies, only about 15% of patients are now classified as idiopathic. Symptomatic cases result from diverse conditions, including cerebral dysgenesis, tuberous sclerosis, phenylketonuria, intrauterine infections, or hypoxic-ischemic injury. Video EEG monitoring and a brain MRI may be needed to determine whether onset of infantile spasms is focal or generalized.

Seizures are characterized by sudden flexor or extensor spasms that simultaneously involve the head, trunk, and limbs. The attacks usually begin before 6 months of age. The EEG is grossly abnormal, showing chaotic high-voltage slow activity with multifocal spikes, a pattern termed *hypsarrhythmia*. The treatment of choice is corticotropin or prednisone; spasms are notoriously refractory to conventional AEDs. Exceptions are topiramate and zonisamide, which have been shown to be an effective alternative to corticotropin in selected cases. Vigabatrin is also effective, especially in children with tuberous sclerosis. Patients on this drug must be monitored for visual field deficits. Although treatment with corticotropin, vigabatrin, zonisamide, or topiramate usually controls spasms and reverses the EEG abnormalities, it has little effect on long-term prognosis. Only about 5% to 10% of children with infantile spasms have normal or near-normal intelligence, and more than 66% have severe disabilities.

Post-traumatic Seizures

Seizures occur within 1 year in about 7% of civilian and in about 34% of military head injuries. The differences relate mainly to the much higher proportion of penetrating wounds in military cases. The risk of developing posttraumatic epilepsy is directly related to the severity of the injury and also correlates with the total volume of brain lost as measured by computed tomography. Depressed skull fractures may or may not be a risk; the rate of posttraumatic epilepsy was 17% in one series but not increased above control levels in another. Head injuries are classified as *severe* if they result in brain contusion, intracerebral or intracranial hematoma, unconsciousness, or amnesia for more than 24 hours or in persistent neurologic abnormalities, such as aphasia, hemiparesis, or dementia. *Mild* head injury (brief loss of consciousness, no skull fracture, no focal neurologic signs, no contusion or hematoma) does not increase the risk of seizures significantly above general population rates.

Nearly 60% of those who have seizures have the first attack in the first year after the injury. In the Vietnam Head Injury Study, however, more than 15% of patients did not have epilepsy until 5 or more years later. Posttraumatic seizures are classified as *early* (within the first 1-2 wk after injury) or *late*. Only recurrent late seizures (those that occur after the patient has recovered from the acute effects of the injury) should be considered *posttraumatic epilepsy*. Early seizures, however, even if isolated, increase the chance of developing posttraumatic epilepsy. About 70% of patients have partial or secondarily generalized seizures. *Impact seizures* occur at the time of or immediately after the injury. These attacks are attributed to an acute reaction of the brain to trauma and do not increase the risk of later epilepsy.

Overt seizures should be treated according to principles reviewed later in this chapter. The most controversial issue concerns the prophylactic use of AEDs to prevent or abort the development of subsequent seizures. Based on the data of Temkin et al LEVEL 1,[3] we recommend treating patients with severe head trauma, as just defined, with an antiepileptic medication for the first week after injury to minimize complications from seizures occurring during acute management. If seizures have not occurred, we do not continue medication beyond the initial 1 to 2 weeks because evidence does not show that longer treatment prevents the development of later seizures or of posttraumatic epilepsy. Data suggest that valproate is less effective than phenytoin in suppressing acute seizures and is also ineffective in preventing the development of posttraumatic epilepsy.

Epilepsia Partialis Continua

Epilepsia partialis continua refers to unremitting focal motor seizures involving part or all of one side of the body. They typically consist of repeated clonic or myoclonic jerks that may remain focal or regional or may march from one muscle group to another, with the extent of motor involvement waxing and waning in endless variation (▶ Video 60.5). In adults, EPC occurs in diverse settings, such as acute strokes, metastases, and metabolic encephalopathies, especially hyperosmolar nonketotic hyperglycemia.

The most distinctive form of EPC, known as the *Rasmussen syndrome*, occurs in children; it usually begins before the age of 10 years. The underlying disorder is chronic focal encephalitis, although an infectious agent has not been identified consistently. About two-thirds of patients report an infectious or inflammatory illness 1 to 6 months before onset of EPC. Generalized tonic-clonic seizures are often the first sign and appear before the EPC establishes itself. About 20% of cases begin with an episode of convulsive status epilepticus. Slow neurologic deterioration inevitably follows, with development of hemiparesis, mental impairment, and, usually, hemianopia. If the dominant hemisphere is affected, aphasia occurs. The EEGs are always abnormal, but findings are not specific, and they frequently do not correlate with clinical manifestations. The MRI may be normal early but later shows unilateral cortical atrophy and signal changes consistent with gliosis. Autoantibodies to the GluR3 protein of the glutamate receptor have been found in some patients, suggesting that autoimmunity may play a role in the pathogenesis of the disorder in some patients, and immunotherapy is sometimes beneficial. The AEDs are usually ineffective in controlling seizures and preventing progression of the disease, as are corticosteroids and antiviral agents. When seizures have not spontaneously remitted by the time there is a severe degree of hemiparesis, functional hemispherectomy can control seizures and leads to substantial intellectual improvement in many patients. Controversy arises in the decision about the best time for hemispherectomy, for example, whether it should be performed earlier before there is serious motor or language impairment.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Management of Epilepsy 61

Carl W. Bazil and Shraddha Srinivasan

KEY POINTS

1. About 60% of patients with a diagnosis of epilepsy are completely controlled with medication; The remainder are refractory to medical treatment.
2. There are many appropriate drugs available; these vary in spectrum of efficacy, but when used for the appropriate epilepsy syndrome, all have approximately equal chance of seizure control.
3. Choice of drug for an individual patient should take into account adverse effect profile, ease of use, potential long-term toxicity (if present), drug interactions, potential effects on coexisting conditions, and cost.
4. When drug treatment results in incomplete seizure control, video-electroencephalogram monitoring should be performed to confirm the diagnosis and determine whether surgical treatment is an option.
5. For patients with refractory seizures, surgical treatment should be considered particularly when a well-defined onset site is localized and when resection is unlikely to result in neurologic deficits.
6. For refractory patients, particularly when surgical treatment is not a good option, treatment with implanted devices (vagus nerve stimulator, responsive neurostimulator, or deep brain stimulator) can result in further seizure reduction.

INTRODUCTION

Seizures are a very common phenomenon; approximately 10% of people will experience one at some point during their lifetime. But seizures may occur for many reasons, only one of which is epilepsy. The classification of epilepsy is explained in depth in Chapter 60; this chapter begins with distinguishing other seizures (particularly acute symptomatic and single seizures) from epilepsy. Once the diagnosis of epilepsy is made, management almost always consists of pharmacologic treatment; however, surgical and device treatment are considerations in patients refractory to medication. Complications of epilepsy and anticonvulsant drugs, psychosocial, and psychiatric issues are also of critical importance in the treatment of any patient with epilepsy.

Acute Symptomatic Seizures

These seizures are caused by, or associated with, an acute medical or neurologic illness (see Chapter 7). A childhood febrile seizure is the most common example of an acute symptomatic seizure, but other frequently encountered causes include metabolic or toxic encephalopathies, head trauma, and acute brain infections.

New Onset Refractory Status Epilepticus or NORSE, is a clinical presentation in a patient without epilepsy or preexisting relevant neurologic disorder, where there is no identifiable acute structural, toxic or metabolic cause. Febrile Infection Related Epilepsy Syndrome or FIRES could be considered a subcategory of NORSE that requires a prior febrile infection, with fever between 2 weeks and 24 hours prior to the onset of refractory status epilepticus, and applies to all ages. The pathophysiology of these two clinical presentations is under investigation. Refer to Chapter 7 on status epilepticus for further reading.

Prophylactic phenytoin has been shown to reduce the frequency of seizures in patients with severe traumatic brain injury from 14% to 4% during the first week after injury LEVEL 2[1]; however, currently, levetiracetam is more often prescribed due to lower incidence of adverse effects and lack of drug-drug interactions; a prospective trial found no difference in seizure recurrence between the two. To the extent that these conditions resolve without permanent brain damage, seizures are usually self-limited. The primary therapeutic concern in such patients should be identification and treatment of the underlying disorder. If antiepileptic drugs (AEDs) are needed to suppress seizures acutely, they generally do not need to be continued after the patient recovers from the causative condition.

The Single Seizure

About 25% of patients with unprovoked seizures come to a physician after a single attack, nearly always a generalized tonic-clonic seizure. Most of these people have no risk factors for epilepsy, have normal findings on neurologic examination, and have a normal first electroencephalogram (EEG). It is important to carefully question these patients regarding possible prior events suggestive of seizure (such as awakening with an unexplained, severe tongue laceration, or losing periods of time) because these may have previously been unrecognized as seizures. A large multicenter randomized study from Italy convincingly demonstrated that AEDs reduce the risk of relapse after the first unprovoked convulsive seizure. Among nearly 400 children and adults, treatment within 7 days of a first seizure was followed by a recurrence rate of 25% at 2 years. In contrast, untreated patients had a recurrence rate of 51%. When patients with previous "uncertain spells" were excluded from the analysis, treatment benefit was still evident, but the magnitude of the effect was reduced to a recurrence rate of 30% in the treated group and 42% in untreated patients.

Although treatment of first seizures reduces the relapse rate even in low-risk patients, there is no evidence that such treatment alters long-term prognosis. In 2015, a new evidence-based guideline for management of adults with a first unprovoked seizure identified the following risk factors for progression to epilepsy: a prior brain insult, an EEG with epileptiform abnormalities, a significant brain-imaging abnormality, and a nocturnal seizure LEVEL 2.[2] Largely for this reason, the new International League Against Epilepsy classification of epilepsy allows for a diagnosis of epilepsy

following only one unprovoked seizure if there is a substantial risk of recurrence. Clinicians' recommendations whether to initiate immediate AED treatment after a first seizure should be based on individualized assessments that weigh the risk of recurrence against the potential side effects of AED therapy and should consider patient preferences. Immediate treatment will not improve the long-term prognosis for seizure remission but will reduce seizure risk over the subsequent 2 years. In most patients with an unprovoked seizure and normal workup, deferring treatment until a second seizure occurs is a reasonable and often preferable decision.

INITIAL DIAGNOSTIC EVALUATION

The diagnostic evaluation has three objectives: to determine if the patient has epilepsy; to classify the type of epilepsy and identify an epilepsy syndrome, if possible; and to define the specific underlying cause. Accurate diagnosis leads directly to proper treatment and formulation of a rational plan of management. The differential diagnosis is considered in Section III, Chapter 6.

Because epilepsy comprises a group of conditions and is not a single homogeneous disorder and because seizures may be symptoms of both diverse brain disorders and an otherwise normal brain, it is neither possible nor desirable to develop inflexible guidelines for what constitutes a standard or minimal diagnostic evaluation. The clinical data from the history and physical examination should allow a reasonable determination of probable diagnosis, seizure and epilepsy classification, and likelihood of underlying brain disorder. Based on these considerations, diagnostic testing should be undertaken selectively.

History and Examination

A complete history is the cornerstone for establishing a diagnosis of epilepsy. Because patients frequently have no or only limited recall of their attacks, it is important to obtain additional information from family members, friends, or other witnesses who have seen the seizure(s). An adequate history should provide a clear picture of the clinical features of the seizures and the sequence in which manifestations evolve; the course of the epileptic disorder; seizure precipitants, such as alcohol or sleep deprivation; risk factors for seizures, such as abnormal gestation, febrile seizures, family history of epilepsy, head injury, encephalitis or meningitis, and stroke; and response to previous treatment. In children, developmental history is particularly important.

In describing the epileptic seizure, care should be taken to elicit a detailed description of any initial change in neurologic function (aura). The aura was once considered to be the warning of an impending attack, but it is actually a focal aware seizure consisting of subjective feelings or experiential phenomena observable only by the patient. Classic examples are paroxysmal fear, déjà vu, or visual distortion. Auras precede many focal unaware or generalized seizures and are experienced by 50% to 60% of adults with epilepsy. An epileptic aura rarely lasts longer than a minute or two; longer "prodromal" symptoms are sometimes described by patients with primary generalized convulsive seizures and are more vague. Auras confirm the suspicion that the seizure begins locally within the brain; they may also provide direct clues about the location or laterality of the focus. Information about later events in the seizure usually are obtained from an observer because of the patient's impaired awareness or frank loss of consciousness or because of postictal amnesia, even though responses to questions during the seizure indicate preserved responsiveness.

FIGURE 61.1 Risk factors for epilepsy. [a]Relative to people without these adverse exposures. [b]Not statistically significant. [c]One pint of 80 proof, 2.5 bottles of wine. (From Hauser WA, Hesdorffer DC. *Epilepsy: Frequency, Causes and Consequences.* New York, NY: Demos; 1990.)

During the seizure itself, a description confirming tonic and/or generalized clonic movements is helpful in confirming that a seizure has, in fact, occurred. Repetitive automatic or purposeless movements (automatisms), sustained postures, presence of myoclonus, and the duration of the seizure help to delineate specific seizure types or epileptic syndromes particularly when a bilateral convulsion has not occurred. Nonspecific postictal findings of lethargy and confusion must be distinguished from focal neurologic abnormalities, such as hemiparesis or aphasia, which could point to the hemisphere of seizure onset.

Information about risk factors (Fig. 61.1) may suggest a particular cause and assist in prognosis. In addition to these risk factors, migraines with auras and depression have been reported to be independent risk factors for unprovoked seizures. Discussion of risk factors with parents may be necessary because children or adults may be uninformed about, or may not recall, early childhood events, such as perinatal encephalopathy, febrile seizures, brain infections, head injuries, or intermittent absence seizures. Age at seizure onset and course of the seizure disorder should be clarified because these features differ in the various epilepsy syndromes.

Findings on neurologic examination are usually normal in patients with epilepsy but occasionally may provide etiologic clues. Focal signs indicate an underlying cerebral lesion. Asymmetry of the hand or face may indicate localized or hemispheric cerebral atrophy contralateral to the smaller side. Phakomatoses are commonly associated with seizures and are suggested by café au lait spots, facial angioma, conjunctival telangiectasia, hypopigmented macules, fibroangiomatous nevi, or lumbosacral shagreen patches.

Electroencephalography

Because epilepsy is fundamentally a physiologic disturbance of brain function, the EEG is the most important laboratory test in evaluating patients with seizures. The EEG helps both to establish the diagnosis of epilepsy and to characterize specific epileptic syndromes. The EEG findings may also help in management and in prognosis (see also Chapter 26).

Epileptiform discharges (spikes and sharp waves) are highly correlated with seizure susceptibility and can be recorded on the first

FIGURE 61.2 Multiple heterotopias in a 33-year-old man with refractory epilepsy, left temporal onset. The larger heterotopia *(arrows)* is likely responsible for seizures; stereo-electroencephalogram would be required to confirm seizure onset. Left, coronal T2. Right, axial T2 IR.

EEG in about 50% of patients with epilepsy. Similar findings are recorded in only 1% to 2% of normal adults and in a somewhat higher percentage of normal children. When multiple EEGs are obtained, epileptiform abnormalities eventually appear in 60% to 90% of adults with epilepsy, but the yield of positive studies does not increase substantially after three or four tests. Prolonged ambulatory or inpatient recordings increase the yield of interictal epileptiform abnormalities both because of the longer sampling times but also because complete sleep-wake cycles are included. It is important to remember, however, that 10% to 40% of patients with epilepsy do not show epileptiform abnormalities on routine EEG. Thus, a normal or nonspecifically abnormal EEG never excludes the diagnosis. Sleep, hyperventilation, photic stimulation, and special electrode placements are routinely used to increase the probability of recording epileptiform abnormalities. Different and distinctive patterns of epileptiform discharge occur in specific epilepsy syndromes as summarized in Chapter 60.

Brain Imaging

Magnetic resonance imaging (MRI) should be performed in all patients older than age 18 years and in children with abnormal development, abnormal findings on physical examination, or seizure types that are likely to be manifestations of symptomatic epilepsy. Computed tomography (CT) will often miss common epileptogenic lesions such as hippocampal sclerosis, cortical dysplasia, and cavernous malformations. Particularly in patients where a subtle structural abnormality is suspected, a 3T or higher study may be warranted. Because CT is very sensitive for detecting brain calcifications, a noncontrast CT (in addition to MRI) may be helpful in patients at risk for neurocysticercosis.

Routine imaging is not necessary for children with idiopathic epilepsy, including the benign focal epilepsy syndromes (see "Benign Epilepsy Syndromes" section in Chapter 60). Brain MRI, although more costly, is more sensitive than CT in detecting potentially epileptogenic lesions, such as heterotopias (Fig. 61.2), cortical dysplasia, hamartomas, differentiated glial tumors, and cavernous malformations. Both axial and coronal planes should be imaged using both T1 and T2 sequences. Gadolinium injection does not increase the sensitivity for detecting cerebral lesions but may assist in differentiating possible etiologies.

Imaging in the coronal plane perpendicular to the long axis of the hippocampus and other variations in technique have improved the detection of hippocampal atrophy and gliosis, findings that are highly correlated with mesial temporal sclerosis (see Fig. 59.8) and an epileptogenic temporal lobe. A focal increased signal particularly in the mesial temporal structures may be seen as a postictal phenomenon as well. An even more sensitive measure of hippocampal atrophy is MRI measurement of the volume of the hippocampus. Hippocampal volume measurements in an individual patient then can be compared with those of normal control subjects. In patients being considered for surgery, interictal positron emission tomography (PET) scans can add valuable localizing information, especially when the MRI scan is negative. Single-photon emission computed tomography (SPECT) scans are also used, although resolution is less than either MRI or PET. Subtraction ictal SPECT coregistered with MRI may also be helpful in localizing the epileptogenic brain region in some cases.

Other Laboratory Tests

Routine blood tests are necessary in newborns and in older patients with acute or chronic systemic disease to detect abnormal electrolyte, glucose, calcium, or magnesium values or impaired liver or kidney function that may contribute to seizure occurrence. They are rarely diagnostically useful in healthy children

or adults. Serum electrolytes, liver function tests, and a complete blood count should be obtained when infectious or metabolic abnormalities are suspected and are also useful as baseline studies before initiating AED treatment.

Any suspicion of meningitis or encephalitis mandates lumbar puncture. Particularly in patients with a more fulminant initial presentation, neoplastic and autoimmune panels should be considered to look for autoimmune encephalitis. Urine or blood toxicologic screens should be considered when otherwise unexplained new-onset generalized seizures occur.

LONG-TERM MONITORING

The most direct and convincing evidence of an epileptic basis for a patient's episodic symptoms is the electrographic recording of a seizure discharge during a typical behavioral attack. Such recordings are especially necessary if the history is ambiguous, EEGs are repeatedly normal or nonspecifically abnormal, and reasonable anticonvulsant treatment has failed. Because most patients have seizures infrequently, routine EEG rarely records an attack. Long-term monitoring permits continuous EEG recording for extended periods, thus increasing the likelihood of recording seizures or interictal epileptiform discharges. Two methods of long-term monitoring are now widely available: inpatient video-EEG monitoring in specialized units, and outpatient video-EEG monitoring with or without simultaneous video. Both have greatly improved diagnostic accuracy and the reliability of seizure classification and both provide continuous recordings through one or more complete sleep-wake cycles, which increases the likelihood of capturing actual ictal events. Each has its own specific advantages and disadvantages. The method chosen depends on the question posed by a particular patient.

Long-term monitoring using video-EEG, usually in a specially designed hospital unit, is the procedure of choice to document psychogenic seizures and other nonepileptic paroxysmal events. It can also establish electrical-clinical correlations, confirm seizure type, and direct further treatment including the localization of epileptogenic foci for possible resective surgery. The emphasis in monitoring units is usually on behavioral events, not interictal EEG activity. The availability of full-time technical and nursing staff ensures high-quality recordings and permits examination of patients during clinical events and helps to ensure patient safety. The AEDs can be reasonably decreased or discontinued in this carefully monitored environment to facilitate seizure occurrence. Computerized detection programs are used to screen EEG continuously for epileptiform abnormalities and subclinical seizures.

Ambulatory EEG is another method for long-term monitoring that is designed for outpatient use in the patient's home, school, or work environment. This is often especially helpful in evaluating children who are usually more comfortable in their familiar and unrestricted home environments. The major limitations of ambulatory monitoring are the variable technical quality resulting from lack of expert supervision and maintenance of electrode integrity, frequent distortion of EEG data by environmental contaminants, and the absence or unreliability of video documentation of behavioral changes. Some systems do allow simultaneous video recordings; however, the camera needs to be carefully positioned at all times to view that patient, and the actual event can be missed due to suboptimal placement. Ambulatory monitoring is most useful in documenting interictal epileptiform activity when routine EEGs have been repeatedly negative or in recording ictal discharges during typical behavioral events. It may also reveal the presence of unrecognized electrographic seizures (particularly absences) if frequent; however, there is a limit of a few day's recording, and infrequent events can be missed. Ambulatory EEG is not a substitute for inpatient video-EEG monitoring, especially when psychogenic seizures are an issue or when patients are being evaluated for epilepsy surgery.

MEDICAL TREATMENT

Therapy of epilepsy has three goals: (1) to eliminate seizures or reduce their frequency to the maximum extent possible, (2) to avoid side effects associated with long-term treatment, and (3) to assist the patient in maintaining or restoring normal psychosocial and vocational adjustment. No medical treatment now available can induce a permanent remission ("cure") or prevent development of epilepsy by altering the process of epileptogenesis.

The decision to institute AED therapy should be based on a thoughtful and informed analysis of the issues involved. Convulsive seizures carry some risk of injury particularly depending not on the seizure itself but on the unpredictable circumstances in which it occurs. Although most patients experiencing a convulsive seizure will recover uneventfully, in rare instances (eg, while swimming or bathing), this could result in death if unwitnessed. However, even relatively minor seizures, especially those associated with loss or alteration of alertness, can be associated with many psychosocial, vocational, and safety ramifications. Finally, the probability of seizure recurrence varies substantially among patients, depending on the type of epilepsy and any associated neurologic or medical problems. Drug treatment, although usually effective, carries some risk of adverse effects, which approaches 30% after initial treatment. Treatment of children raises additional issues, especially the unknown effects of long-term AED use on brain development, learning, and behavior.

These considerations mean that although drug treatment is indicated and is beneficial for nearly all patients with epilepsy, certain circumstances call for AEDs to be deferred or used only for a limited time. As a rule of thumb, AEDs should be prescribed when the potential benefits of treatment clearly outweigh possible adverse effects of therapy.

Antiepileptic Drugs

Selection of Antiepileptic Drugs

Selection of an appropriate AED starts with the one most likely to result in seizure freedom for the epilepsy syndrome. Many high-quality studies over several decades have failed to determine a clearly more effective drug when used for the correct seizure type. Two randomized, double-blind nationwide collaborative Veterans Administration Cooperative Studies (1985 and 1992) compared the effectiveness of the then available major AEDs for treating new-onset epilepsy. In the 1985 study, carbamazepine, phenytoin, primidone, and phenobarbital were equally effective in controlling complex partial and secondarily generalized seizures [LEVEL 1].[3] In the 1992 study, carbamazepine was slightly more effective than valproate in treating complex partial seizures, but both drugs were of equal efficacy in controlling secondarily generalized seizures [LEVEL 1].[4] These studies also demonstrated that despite their relatively uniform ability to suppress seizures, the drugs had different risks of adverse effects. Randomized trials in patients with focal seizures have also been conducted comparing the effectiveness of gabapentin,

lamotrigine, topiramate, levetiracetam, zonisamide, or oxcarbazepine to that of carbamazepine and/or phenytoin. None has shown definite superiority, although many have demonstrated that the newer agents have improved tolerability. The Standard and New Antiepileptic Drugs trial, a large open-label study, randomized patients with focal epilepsy to carbamazepine, lamotrigine, oxcarbazepine, or topiramate. Lamotrigine had a slight advantage in time to treatment failure, but as in previous comparative studies, the differences among agents in terms of effectiveness were minimal LEVEL 1.[5] Many smaller trials have directly compared various drugs against each other with similar findings; although there may be differences in tolerability, there are no clear advantages in efficacy when an appropriate agent is used at a therapeutic dose LEVEL 1.[6] Overall, for new-onset focal seizures carbamazepine, lamotrigine, gabapentin, levetiracetam, oxcarbazepine, pregabalin, and zonisamide are considered the most reasonable options.

For generalized onset seizures, valproate was long considered the gold standard of treatment; however, due mainly to tolerability and safety concerns lamotrigine, levetiracetam, topiramate, and zonisamide are now considered reasonable alternatives. A second arm of the Standard and New Antiepileptic Drugs trial compared the effectiveness of valproate, lamotrigine, and topiramate in patients with all types of generalized or unclassified seizures. Valproate was found to be slightly more effective overall, especially for idiopathic epilepsy, although the differences were minimal LEVEL 2.[7] Phenytoin, carbamazepine, eslicarbazepine, and oxcarbazepine are useful in suppressing generalized tonic-clonic seizures, but the response is less predictable than that with valproate. Carbamazepine, phenytoin, gabapentin, and lamotrigine can aggravate myoclonic seizures; all of these except lamotrigine also sometimes exacerbate absence seizures. Ethosuximide is as effective as valproate in controlling absence seizures and has fewer side effects. Ethosuximide is ineffective against tonic-clonic seizures, however, so its main use is as an alternative to valproate in patients who have only absence seizures.

Although not always initially approved in this group, most AEDs effective in adults have been subsequently proven effective for the same seizure type in children and, when not, can be tried off-label so long as sufficient safety data are present. Evidence also suggests that lamotrigine and topiramate are effective for adjunctive treatment of idiopathic generalized epilepsy in adults and children as well as treatment of the Lennox-Gastaut syndrome LEVEL 1.[8]

Clobazam was initially approved in the United States only for add-on therapy in severe epilepsies such as Lennox-Gastaut syndrome. It is also effective in focal epilepsies that are refractory to other medications and has been widely prescribed worldwide for this indication. Cannabidiol has been approved for treatment of seizures in Lennox-Gastaut and Dravet syndrome. Although this compound has gained considerable interest in the popular press, randomized trials show that, although it shows some efficacy in these hard-to-treat syndromes, it is not clearly greater than other available compounds, and adverse effects are comparable or possibly worse. Vigabatrin was approved by the U.S. Food and Drug Administration (FDA) for treating infantile spasms in children 1 month to 2 years of age.

Of the more recently introduced antiepileptic medications, lacosamide, eslicarbazepine, perampanel, brivaracetam, and cenobamate have been approved for use in focal epilepsies refractory to other medications, and rufinamide was additionally approved to treat seizures associated with Lennox-Gastaut syndrome.

Elderly patients with epilepsy require special consideration because of age-related changes in both pharmacokinetic profiles and pharmacodynamic characteristics. Relevant physiologic changes include decreased hepatic metabolism and plasma protein binding, decreased renal clearance, and slower gastrointestinal motility and absorption. There is greater sensitivity to both desirable and undesirable effects on brain function. Additionally, concurrent medical illnesses are common, and as a result, most elderly patients take multiple drugs, which increase the likelihood of clinically significant drug interactions. Several clinical trials involving elderly patients, including the large Veterans Administration cooperative study, have found that lamotrigine and gabapentin are better tolerated than carbamazepine, although, as in younger patients, differences in effectiveness, if any, are small. For practical reasons, clinicians tend to use agents with few or no drug interactions in this population (particularly gabapentin, lamotrigine, levetiracetam, and lacosamide).

Because there are many effective drugs available particularly for focal seizures, the choice is based on many factors including particular adverse effect profile, ease of use, speed of titration, drug-drug interactions, long-term safety, and cost. Any attempt to choose "first choice" is therefore necessarily somewhat arbitrary because individual factors may make one drug inappropriate in one individual when its overall profile is well suited for another. **Table 61.1** lists drugs most likely to be appropriate for first use, those in which

TABLE 61.1 Drugs[a] Used in Treating Different Types of Seizures

Type of Seizure	Drugs of First Choice	Drugs to Consider in Selected Patients	Drugs Generally Reserved for Highly Refractory Patients
Focal Seizures			
Focal and secondarily generalized	Carbamazepine, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, gabapentin, zonisamide	Eslicarbazepine, topiramate, lacosamide, valproate, clobazam	Phenytoin, primidone, phenobarbital, perampanel, brivaracetam, felbamate, cenobamate
Primary Generalized Seizures			
Generalized tonic-clonic	Lamotrigine, topiramate, levetiracetam, valproate, zonisamide	Eslicarbazepine, clobazam, carbamazepine, oxcarbazepine	Phenytoin, perampanel, felbamate
Absence	Valproate, ethosuximide	Lamotrigine, zonisamide, clobazam	Felbamate
Myoclonic	Valproate, clonazepam, clobazam, levetiracetam	Zonisamide	
Tonic/atonic	Valproate, clonazepam, clobazam, zonisamide	Felbamate, rufinamide	Cannabidiol

[a]Not all drugs have U.S. Food and Drug Administration approval for listed uses.

specific patients may benefit, and those whose overall profile makes them generally suitable only after failing other options.

Adverse Effects of Antiepileptic Drugs

All AEDs have undesirable effects in some patients. Although interindividual variation occurs, most adverse drug effects are mild and dose related. Many are common to virtually all AEDs, especially when treatment is started. These include sedation, mental dulling, impaired memory and concentration, mood changes, gastrointestinal upset, and dizziness. The incidence of particular adverse effects varies with the individual agent. In general, sedation and cognitive effects are less likely with lamotrigine, gabapentin, levetiracetam, or lacosamide than with older agents, especially in elderly persons. Some other adverse effects are relatively specific for particular drugs.

Dose-Related Adverse Effects

These typically appear when a drug is first given or when the dosage is increased. They usually, but not always, correlate with blood concentrations of the parent drug or major metabolites (Table 61.2). Dose-related side effects are always reversible on lowering the dosage or discontinuing the drug. An exception to this is the peripheral vision loss with vigabatrin, which may progress despite stopping the drug. Adverse effects frequently determine the limits of treatment with a particular drug and have a major influence on compliance with the prescribed regimen. Because dose-related side effects are broadly predictable, they are often the major differentiating feature in choosing among otherwise equally effective therapies.

Idiosyncratic Reactions

Idiosyncratic responses account for most serious and virtually all life-threatening adverse reactions to AEDs. Many AEDs can cause similar serious side effects (see Table 61.2), but with the exception of rash, these are fortunately rare. For example, the risk of carbamazepine-induced agranulocytosis or aplastic anemia is about 2 per 575,000; with felbamate, the risk of aplastic anemia may be as high as 1 per 5,000. Idiosyncratic reactions are not dose related; rather they arise either from an immune-mediated reaction to the drug or from poorly defined individual factors, largely genetic, that convey an unusual sensitivity to the drug. An example of the genetic mechanism is valproate-induced fatal hepatotoxicity. Valproate, like most AEDs, is metabolized in the liver, but several biochemical pathways are available to the drug. Clinical and experimental data indicate that one of these pathways results in a hepatotoxic compound that may accumulate and lead to microvesicular steatosis with necrosis. The extent to which this pathway is involved in biotransformation is age dependent and promoted by concurrent use of other drugs that are eliminated in the liver. Thus, most patients who have had fatal hepatotoxicity were younger than 2 years of age and treated with polytherapy (Table 61.3). In addition, most had severe epilepsy associated with mental retardation, developmental delay, or congenital brain anomalies. No hepatic deaths have occurred in persons older than 10 years treated with valproate alone.

No laboratory test, certainly not untargeted routine blood monitoring, identifies individuals specifically at risk for valproate hepatotoxicity or any other drug-related idiosyncratic reaction. Clinical data, however, permit identification of groups of patients at increased risk for serious adverse drug reactions, including patients with known or suspected metabolic or biochemical disorders, a history of previous drug reactions, and medical illnesses affecting hematopoiesis or liver and kidney function.

TABLE 61.2 Toxicity of Antiepileptic Drugs

Dose-Related Adverse Effects	
Systemic Toxicity	**More Common With**
Gastrointestinal (dyspepsia, nausea, diarrhea)	Valproate, phenobarbital, phenytoin, carbamazepine, oxcarbazepine
Benign elevation in liver enzymes	Valproate, phenobarbital, phenytoin, carbamazepine, oxcarbazepine
Benign leukopenia	Carbamazepine, oxcarbazepine
Gingival hypertrophy	Phenytoin
Weight gain	Valproate, gabapentin, pregabalin
Anorexia and weight loss	Felbamate, topiramate, zonisamide
Hair loss, change in hair texture	Valproate
Hirsutism	Phenytoin, valproate
Hyponatremia (typically benign)	Carbamazepine, oxcarbazepine, eslicarbazepine
Coarsening of facial features	Phenytoin
Osteoporosis	Phenytoin, phenobarbital, carbamazepine, valproate
Impotence	Phenobarbital, phenytoin, carbamazepine, topiramate
Neurologic Toxicity	**More Common With**
Drowsiness, sedation	Phenobarbital, benzodiazepines
Impaired cognition	Phenobarbital, topiramate
Depression and mood changes	Phenobarbital, levetiracetam, perampanel, topiramate
Insomnia	Felbamate
Peripheral visual field restriction	Vigabatrin
Dizziness/vertigo	Carbamazepine, oxcarbazepine, lamotrigine, phenobarbital, phenytoin
Nystagmus, diplopia	Carbamazepine, oxcarbazepine, lamotrigine, phenobarbital, phenytoin
Sensory neuropathy	Phenytoin
Idiosyncratic Reactions	
Rash (rare with clobazam, gabapentin, levetiracetam, pregabalin, valproate)	
Stevens-Johnson syndrome (especially phenobarbital, phenytoin, carbamazepine, lamotrigine)	
Aplastic anemia (especially felbamate)	
Hepatic failure (especially felbamate, valproate)	
Pancreatitis (especially valproate)	
Thrombocytopenia (especially valproate)	

Rash can occur with virtually any drug, and rarely, this results in Stevens-Johnson syndrome. The frequency of severe rash is about the same with carbamazepine, phenytoin, phenobarbital, and (if started slowly over several weeks) lamotrigine. Certain Asian populations are more prone to rash with these agents, associated with a human leukocyte antigen B subtype. There is some cross-reactivity among these drugs so that a patient who develops a rash with one has a slightly increased risk of developing a rash with another. Rash is unusual with valproate, gabapentin, pregabalin, or levetiracetam, although it is important to remember that allergic reaction can occur not only to the drug itself but also to inert ingredients such as dyes.

TABLE 61.3 Effect of Age and Treatment on Risk of Developing Fatal Valproate Hepatotoxicity[a]

Age	Monotherapy	Polytherapy
<2 y	1/7,000	1/500
>2 y	1/80,000	1/25,000

[a]Modified from Dreifuss FE, Santilli N, Langer DH, Sweeney KP, Moline KA, Menander KB. Valproic acid hepatic fatalities: a retrospective review. *Neurology*. 1987;37:379-385.

To date, life-threatening idiosyncratic effects have not been reported with gabapentin, pregabalin, topiramate, oxcarbazepine, levetiracetam, or lacosamide.

Antiepileptic Drug Pharmacology

Table 61.4 provides summary information about dose requirements, pharmacokinetic properties, and therapeutic concentration ranges for the major AEDs available in the United States. Of patients with epilepsy, 60% to 70% achieve satisfactory control of seizures with currently available AEDs, but the remainder continues to have disabling seizures despite optimal medical therapy.

Treatment should start with a single AED chosen according to the type of seizure or epilepsy syndrome and then be adjusted as necessary, by considerations of side effects, required dosing schedule, and cost. Phenytoin, phenobarbital, gabapentin, zonisamide, and levetiracetam can be loaded acutely when necessary although there can be transient adverse effects. Most drugs are initially studied in refractory patients with focal epilepsy, and therefore, initial approval is sometimes restricted; however, subsequent experience as well as randomized trials confirms that all are effective as initial monotherapy. In the absence of status epilepticus (see Chapter 6), AEDs are usually started at low dosages to minimize acute toxicity. They can then be increased according to the patient's tolerance and the drug's pharmacokinetics. The initial target dose should produce a serum concentration in the low- to midtherapeutic range. Further increases can then be titrated according to the patient's clinical progress, which is measured mainly by seizure frequency and the occurrence of drug side effects. A drug should not be judged a failure unless seizures remain uncontrolled at the maximal tolerated dosage, regardless of the blood level.

Dosage changes generally should not be made until the effects of the drug have been observed at steady-state concentrations (a time about equal to five drug half-lives). If the first drug is ineffective, an appropriate alternative should be gradually substituted (see Table 61.1). Combination treatment using two drugs should be attempted only when monotherapy with at least one,

TABLE 61.4 Antiepileptic Drugs: Dosage and Pharmacokinetic Data[a]

Drug	Usual Adult Dose 24 h (mg)	Half-life (h)	Usually Effective Plasma Concentration (μg/mL)	Time-to-Peak Concentration (h)	Bound Fraction (%)
Phenobarbital[b]	90-180	100	15-40	2-8	45
Phenytoin[b,c]	300-400	22	10-20	3-8	90-95
Carbamazepine[b,c]	800-1,600	8-22	8-12	4-8	75
Valproate[b,c]	1,000-3,000	15-20	50-120	3-8	80-90
Ethosuximide	750-1,500	60	40-100	3-7	<5
Felbamate	2,400-3,600	14-23	20-140	2-6	25
Gabapentin[c]	1,800-3,600	5-7	4-16[d]	2-3	<5
Lamotrigine[c]	100-500	12-60[e]	2-16[d]	2-5	55
Topiramate[c]	200-400	19-25[e]	4-10[d]	2-4	9-17
Vigabatrin	1,000-3,000	5-7	NE	1-4	5
Levetiracetam[b,c]	1,000-3,000	6-8	5-45[d]	1	<10
Oxcarbazepine[c]	900-2,400	8-10[f]	10-35[d]	3-13	40[f]
Zonisamide	100-600	24-60[e]	10-40[d]	2-6	40
Pregabalin[c]	150-600	5-7	NE	1	<5
Lacosamide[b]	200-400	12-16	5-10[d]	1-4	<15
Rufinamide	2,400-3,200	6-10	NE	4-6	34
Clobazam	10-60	36-42	NE	0.5-4	80-90
Perampanel	8-12	105	NE	0.5-2.5	95
Eslicarbazepine	800-1600	13-20	NE	1-4	<40
Brivaracetam[b]	50-200	9	NE	1	<20
Cannabidiol	700-1400	56-62	NE	2.5-5	>94
Cenobamate	200	50-60	NE	1-4	60

Abbreviation: NE, not established.
[a]Drugs are listed roughly in order of commercial availability.
[b]Intravenous formulation available.
[c]Extended release formulation available.
[d]Not established; corresponds to usual range in patients treated with recommended dose.
[e]Highly dependent on concurrently administered drugs.
[f]Of metahydroxy derivative, the active metabolite.

and preferably two, primary AEDs fails. Combination therapy is sometimes effective, but the price of improved seizure control is often additional drug toxicity. Sometimes, combination therapy with relatively nonsedating drugs (eg, carbamazepine, lamotrigine, gabapentin, or levetiracetam) is preferable to high-dose monotherapy with a sedating drug (eg, phenobarbital or primidone). When used together, carbamazepine and lamotrigine result in a pharmacodynamic interaction that often produces neurotoxicity at dosages that are usually well tolerated when either drug is used alone.

Dosing intervals should ideally be less than one-third to one-half the drug's half-life to minimize fluctuations between peak and trough blood concentrations. Large fluctuations can result in drug-induced side effects at peak levels and in breakthrough seizures at trough concentrations. Sometimes, however, a drug has a relatively long pharmacodynamic half-life, so that twice a day dosing is reasonable even if the pharmacokinetic half-life is short. This is typically the case with valproate, pregabalin, gabapentin, and levetiracetam. Extended-release formulations of most commonly used AEDs are available, which allow less frequent dosing and decreased peak and trough levels, thereby potentially improving tolerability and compliance. Bioavailability is not necessarily equivalent to immediate-release formulations (particularly for lamotrigine and valproate), and different extended-release delivery systems with alternate manufacturers of the same drug can also create variation in peak and trough levels as well as in total absorption.

Therapeutic drug monitoring has greatly improved the care of patients with epilepsy, but published therapeutic ranges are only guidelines. Most patients whose drug concentrations are within a standard therapeutic range usually achieve adequate seizure control with minimal side effects, but notable exceptions occur. Some patients develop unacceptable side effects at "subtherapeutic" concentrations; other obtain maximal seizure control only at "toxic" concentrations without adverse effects.

Determining serum drug concentrations when seizure control has been achieved, when seizures recur, or when side effects appear can assist management decisions. Drug levels are also useful in documenting compliance and in assessing the magnitude and significance of known or suspected drug interactions. Therapeutic drug monitoring is an essential guide to treating neonates, infants, young children, elderly persons, and patients with diseases (eg, liver or kidney failure) or physiologic conditions (eg, pregnancy) that alter drug pharmacokinetics. Although the total blood concentrations that are routinely reported are satisfactory for most indications, unbound (free) concentrations are useful when protein binding is altered, as in renal failure, pregnancy, extensive third-degree burns, and combination therapy using two or more drugs that are highly bound to serum proteins (eg, phenytoin and valproate).

Specific Drugs

Phenytoin

Phenytoin is thought to control seizures through voltage-dependent blockade of sodium channels. It is unique among AEDs due to nonlinear elimination at therapeutically useful serum concentrations. That is, hepatic enzyme systems metabolizing phenytoin become increasingly saturated at plasma concentrations greater than 10 to 12 μg/mL, and metabolic rate approaches a constant value at high concentrations. With increasing doses, phenytoin plasma concentrations rise exponentially (**Fig. 61.3**) so that steady-state concentration at one dose cannot be used to predict directly the steady-state concentration at a higher dose. Clinically, this requires cautious titration within the therapeutic range, using dose increments of 30 mg to avoid toxic effects. Phenytoin is also a strong enzyme inducer, therefore affecting the metabolism of many coadministered agents including many other AEDs. It is also highly protein bound, and free (active) levels can be unexpectedly high when coadministered with other highly protein-bound drugs or in medical conditions where protein binding sites are low (hypoalbuminemia). These complicated pharmacokinetic properties, along with relatively higher number of adverse effects and long-term toxicities compared with other AEDs, means that phenytoin is no longer a drug of first choice in most patients.

FIGURE 61.3 Phenytoin dose concentration curves from three representative adult patients. Note the markedly nonlinear relationship in the 200- to 400-mg dose range. Careful dose titration is necessary in this portion of the curve to avoid neurotoxicity. Abbreviations: K_m, Michaelis-Menten constant; V_{max}, maximum elimination rate.

Carbamazepine

Carbamazepine induces activation of the enzymes that metabolize it. The process, termed *autoinduction*, is time dependent. When carbamazepine is first introduced, the half-life approximates 30 hours. With increasing hepatic clearance in the first 3 to 4 weeks of therapy, however, the half-life shortens to 11 to 20 hours. As a result, the starting dose should be low and then increased gradually, and dosing should be frequent (3 or 4 times daily). Extended-release formulations permit twice a day administration. The principal metabolite is carbamazepine-10,11-epoxide, which is pharmacologically active. Under certain circumstances (eg, when coadministered with valproate or felbamate), the epoxide metabolite accumulates selectively, thereby producing neurotoxic effects even though the plasma concentration of the parent drug is in the therapeutic range or even low.

Oxcarbazepine

Oxcarbazepine and its active enantiomer, *eslicarbazepine*, are structurally similar to carbamazepine but are metabolized by a different pathway. As a result, there is no epoxide metabolite that is responsible for some of the adverse effects of carbamazepine. Although individual patients may tolerate oxcarbazepine or eslicarbazepine better than carbamazepine, the overall profiles of the drugs are similar, including development of leukopenia, mild increase in hepatic enzymes, and hyponatremia (all usually transient, asymptomatic, and benign). Pharmacologic half-life of the active metabolite of oxcarbazepine, a metahydroxy derivative, is 8 to 10 hours. Clinical studies support twice-daily dosing for oxcarbazepine, although peak toxicity can occur when this is done at higher dosages. The half-life of eslicarbazepine is longer (13-20 h) allowing once daily dosing.

Valproate

Valproate is highly bound to plasma proteins (like phenytoin), but the binding is concentration dependent and nonlinear. The unbound fraction increases at plasma concentrations greater than 75 μg/mL because protein-binding sites become saturated. For example, doubling the plasma concentration from 75 to 150 μg/mL can result in a more than sixfold rise in concentration of free drug (from 6.5 to 45 μg/mL). Therefore, as the dose of valproate is increased, side effects may worsen rapidly because of the increasing proportion of unbound drug. Furthermore, adverse effects may vary in the course of a single day or from day to day because concentrations of unbound drug fluctuate despite seemingly small changes in total blood levels. Additionally, circulating fatty acids displace valproate from protein-binding sites. If fatty acid levels are high, the amount of unbound valproate increases. Lamotrigine and felbamate prolong the half-life of valproate, and therefore, a reduced dosage is typically necessary when these drugs are added.

Gabapentin

Gabapentin requires an intestinal amino acid transport system for absorption. Because the transporter is saturable, the percentage of drug that is absorbed after an oral dose decreases with increasing dosage. More frequent dosing schedules using smaller amounts may therefore be necessary to increase blood levels. When dosages above 3,600 mg/day are used, blood levels can be helpful in demonstrating that an increase in dosage is reflected in an increased serum concentration. Gabapentin does not interact to any clinically significant degree with any other drugs, which makes it especially useful when AED polytherapy is necessary and in patients with medical illnesses that also require drug treatment. It is not metabolized in the liver, but as it is excreted unchanged by the kidneys, dose adjustment is required in patients with renal failure. Gabapentin binds to a subunit of a calcium channel thereby reducing calcium influx in overactive neurons. *Pregabalin* is structurally and mechanistically similar to gabapentin but does not show dose-dependent absorption. It has increased potency compared with gabapentin and can be effective with twice-daily dosing.

Lamotrigine

Lamotrigine is highly sensitive to coadministration of many other AEDs. Enzyme-inducing agents, such as phenytoin and carbamazepine, decrease the half-life of lamotrigine from 24 to 16 hours (or less) as do oral contraceptive agents. In contrast, enzyme inhibition by valproate increases the half-life of lamotrigine to 60 hours. Therefore, lamotrigine dosing depends very much on whether it is used as monotherapy or in combination with other AEDs. Lamotrigine concentrations are also lowered by administration of oral contraceptives, and levels can decrease dramatically during the latter months of pregnancy requiring frequent monitoring and dose adjustment. Lamotrigine has little or no effect on other classes of drugs. Rash occurs in about 10% of patients; it is more common in children and rarely leads to Stevens-Johnson syndrome. The incidence of rash can be minimized by slow titration schedules.

Levetiracetam

Levetiracetam, like gabapentin, has no appreciable interactions with other drugs and therefore has advantages in medically complicated patients. The plasma half-life is 6 to 8 hours, but clinical trials support twice-daily dosing, possibly owing to a longer pharmacodynamic half-life. Metabolism occurs in the liver, and there is also renal clearance. Adverse effects are generally mild and self-limited, although mood changes and even psychosis occur in a small subset of patients. No life-threatening idiosyncratic reactions have yet been described. It binds to a synaptic vesicle protein thereby limiting neurotransmitter release; this is felt to be its mechanism of seizure control.

Brivaracetam

Brivaracetam is structurally and mechanistically related to levetiracetam. Unlike levetiracetam, it does have some drug-drug interactions, notably increasing levels of phenytoin and carbamazepine epoxide. Adverse effects on mood are thought to be less common.

Topiramate

Topiramate is affected by other AEDs taken concurrently. Carbamazepine, phenytoin, and phenobarbital shorten its half-life; valproate has little effect. Topiramate does not affect most other drugs, although phenytoin blood levels may increase by 25%. Adverse cognitive effects, especially word-finding difficulty and impaired memory, frequently limit the dosage patients can tolerate. These are usually dose dependent and can be minimized with slow titration schedules. Cognitive effects are also less common in monotherapy. Glaucoma, anhydrosis, and renal stones occur rarely. Doses above 400 mg/day do not usually lead to better seizure control but are associated with an increasing incidence of side effects.

Zonisamide

Zonisamide is affected by other drugs that induce hepatic enzymes. As monotherapy, zonisamide's half-life is about 60 hours. When coadministered with enzyme-inducing drugs, its half-life

can be reduced to 24 hours. In either case, once-daily dosing is appropriate. Although its metabolism occurs primarily in the liver, zonisamide itself does not appear to affect other drugs. Rash, renal stones, and anhydrosis are rare side effects.

Felbamate

Felbamate has a much higher risk of serious adverse reactions, including aplastic anemia and hepatic failure, than other AEDs. The actual risk has been difficult to estimate but is probably between 1 per 5,000 and 1 per 20,000 exposures. For this reason, its use is currently restricted to patients who are refractory to other agents and in whom the risk of continued seizures outweighs the risk of side effects. Use of felbamate is also limited by other common but less serious adverse effects, including anorexia, weight loss, insomnia, and nausea, and by numerous complex drug interactions. Nonetheless, felbamate remains useful in cases of severe epilepsy such as Lennox-Gastaut syndrome.

Lacosamide

Lacosamide enhances the slow inactivation of sodium channels without affecting fast inactivation. It is approved for the treatment of partial-onset seizures. It may prolong the PR interval, which can result in cardiac conduction problems. A baseline electrocardiogram is suggested prior to initiating this drug in patients at risk for cardiac disease. Lacosamide is generally well tolerated and has no appreciable drug-drug interactions making it particularly useful as an add-on drug in refractory patients.

Rufinamide

Rufinamide is a triazole derivative whose exact mechanism is unknown. In vitro prolongs the inactive state of the sodium channels, thereby limiting repetitive firing of sodium ion–dependent action potentials mediating anticonvulsant effects. Its use is limited largely to refractory generalized epilepsies, especially in controlling tonic seizures.

Clobazam

Clobazam has been used in many countries around the world for both focal and generalized seizures, but it was only FDA approved in the United States for adjunctive treatment of Lennox-Gastaut syndrome. It is widely used off-label as monotherapy or adjunctive treatment for partial seizures. As a benzodiazepine there may be some increased risk of tolerance compared to other anticonvulsant drugs; however, this seems to occur much less frequently than with agents such as diazepam or lorazepam. There are also anxiolytic properties making this a useful agent when this is a comorbid condition. Serious reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported.

Perampanel

Perampanel, which is FDA approved as an adjunctive medication in partial seizures, has a unique mechanism of action in that it is the first noncompetitive antagonist of the AMPA glutamate receptor. It comes with a boxed warning of dose-related serious neuropsychiatric events including homicidal thoughts and aggression. Being both an inducer and a substrate of the cytochrome P450 3A4 enzymes, drug interactions with other antiseizure medications exist.

Cannabidiol

Cannabidiol is a plant-based extract approved for treatment of refractory seizures associated with the Lennox-Gastaut syndrome and Dravet syndrome. Although placebo-controlled trials show efficacy in these conditions, it is not clearly more effective than other available compounds, adverse effects can occur, and as an extract administered in oil, absorption can be erratic. It is therefore reserved for when other treatments have failed to achieve sufficient results.

Cenobamate

Cenobamate is effective for focal onset seizures; some patients with refractory seizures became seizure free in clinical trials. Slow titration is required to reduce the possibility of severe reactions (drug reaction with eosinophilia and systemic symptoms). It may effect levels of several other AEDs including lamotrigine, carbamazepine, phenytoin and clobazam. It should be used with caution in patients with cardiac disease due to shortening of the QT interval.

Use of Generic Equivalents

Generic equivalents are available for the majority of anticonvulsant drugs, and these represent a more cost-effective treatment for most patients. Some degree of variability exists when changing between AED manufacturers, particularly with extended release preparations. Some studies suggest variability is not unlikely with drug peak and trough (due to variability in absorption time); however, total drug absorption is affected rarely. When in doubt, change in manufacturer should be limited whenever possible for an individual patient, and therapeutic drug monitoring can ensure no significant change in steady state level.

Discontinuing Antiepileptic Drugs

Epidemiologic studies indicate that 60% to 70% of patients with epilepsy become free of seizures for at least 5 years within 10 years of diagnosis. Similarly, prospective clinical trials of treated patients whose seizures were in remission for 2 years or more showed that a nearly identical percentage of patients remained seizure free after drug withdrawal LEVEL 1.[9] Chance of recurrence continues to decline with seizure freedom for 2 to 5 years. These studies also identified predictors that permit patients to be classified as being at low or high risk for seizure relapse after drug therapy ends. The risk of relapse was high if patients required more than one AED to control seizures, if seizure control was difficult to establish, if the patient had a history of generalized tonic-clonic seizures, and if the EEG was significantly abnormal when drug withdrawal was considered. Continued freedom from seizures is favored by longer seizure-free intervals (>4 y) before drug withdrawal is attempted, few seizures before remission, monotherapy, normal EEG, and no difficulty establishing seizure control.

All benign epilepsy syndromes of childhood carry an excellent prognosis for permanent drug-free remission. In contrast, juvenile myoclonic epilepsy has a high rate of relapse when drugs are discontinued, even in patients who have been seizure free for many years (at least 30%). The prognosis for most other epilepsy syndromes is largely unknown.

Discontinuing AED therapy in appropriate patients can be considered when they have been seizure free for at least 2 years. The most powerful argument for stopping AEDs is concern about long-term systemic and neurologic toxicity, which can be insidious and not apparent for many years after a drug has been introduced. On the other hand, however, is the concern of the patient or family about seizure recurrence. Even a single seizure can have disastrous psychosocial and vocational consequences,

particularly in adults. Therefore, the decision to withdraw drugs must be weighed carefully in the light of individual circumstances. For example, a woman who is considering pregnancy and has been seizure free for many years may wish to attempt withdrawal of AEDs before conceiving or a person who develops renal stones on topiramate could attempt withdrawal rather than change to another agent. If a decision is made to discontinue AEDs, we favor slow withdrawal, over 3 to 6 months, but this recommendation is controversial because few studies of different withdrawal rates have been conducted.

Reproductive Health Issues

Gender-based differences in AED pharmacokinetics, sex steroid hormones, and reproductive life events raise special issues for women with epilepsy. The management of pregnancy in a woman with epilepsy is discussed in detail in Chapter 129. This section focuses on the effects of reproductive hormones on seizures and on the effects of seizures and AEDs on reproductive health.

Although the prevalence of epilepsy is not higher in women, epilepsy in women can be specially affected by changes in reproductive steroids. Estrogen is a proconvulsant drug in animal models of epilepsy, whereas progesterone and its metabolites have anticonvulsant effects. Ovarian steroid hormones act at the neuronal membrane and on the genome to produce immediate and long-lasting effects on excitability. Estrogen reduces γ-aminobutyric acid–mediated inhibition, whereas progesterone enhances γ-aminobutyric acid effects. Estrogen also potentiates the action of excitatory neurotransmitters in some brain regions and increases the number of excitatory synapses. These dynamic and significant changes in neuronal excitability are observed with changes in estrogen and progesterone concentrations similar to those observed in the human menstrual cycle.

Approximately one-third of women with epilepsy report patterns of seizure occurrence that relate to phases of the menstrual cycle (*catamenial seizures*). Women with catamenial seizures indicate that seizures are more frequent, or more severe, just before menstruation and during the time of menstrual flow. In some women, seizures also increase at ovulation. These are times in the menstrual cycle when estrogen levels are relatively high and progesterone concentration is relatively low. Several small clinical trials have described benefit from chronic progesterone therapy in women with catamenial seizure patterns. Changes in seizures related to puberty and menopause are not well understood.

The pharmacokinetics of some AEDs can complicate epilepsy management in women. The AEDs that induce activity of the cytochrome P450 enzyme system (carbamazepine, phenytoin, phenobarbital, primidone, and, to a lesser extent, topiramate, clobazam, eslicarbazepine, oxcarbazepine, and perampanel) interfere with the effectiveness of estrogen-based hormonal contraception. In women taking these drugs, the metabolism and binding of contraceptive steroids is enhanced, thus reducing the biologically active fraction of steroid hormone. The failure rate of oral contraceptive pills exceeds 6% per year in women taking enzyme-inducing AEDs, in contrast to a failure rate of less than 1% per year in medication-compliant women without epilepsy. A woman motivated to avoid pregnancy should consider using a contraceptive preparation containing 50 μg or more of an estrogenic compound or using an additional barrier method of contraception. Alternatively, she should discuss with her physician the possibility of selecting an AED that does not alter steroid metabolism or binding. During pregnancy, clearance of many AEDs increases, requiring increasing doses to maintain an effective level. This is particularly true not only of lamotrigine, phenytoin, and carbamazepine but also can occur with levetiracetam, oxcarbazepine, and possibly other agents. Therapeutic monitoring monthly during pregnancy is recommended. If the dose has been substantially increased, this should be lowered over several weeks following delivery to avoid toxicity.

Reproductive health may be compromised in both women and men with epilepsy. Fertility rates for men and women with epilepsy are one-third to two-thirds those of men and women without epilepsy. Lower birth rates cannot be explained on the basis of lower marriage rates because marriage rates for women with epilepsy are now similar to those of nonepileptic women. Reduced fertility appears to be the direct result of a disturbance in reproductive physiology.

Men and women with epilepsy show a higher than expected frequency of reproductive endocrine disturbances. These include abnormalities both in the cyclic release and concentration of pituitary luteinizing hormone and prolactin and in the concentration of gonadal steroid hormones. Some of these abnormalities are likely to be a consequence of seizure activity. The AEDs can also alter concentrations of gonadal steroids by affecting steroid hormone metabolism and binding. The AEDs that increase steroid metabolism and binding reduce steroid hormone feedback at the hypothalamus and pituitary. The AEDs that inhibit steroid metabolism (eg, valproate) increase concentrations of steroid hormones, particularly androgens.

The polycystic ovary syndrome (PCOS) is a gynecologic disorder affecting approximately 7% of reproductive-age women. Women with epilepsy are at risk for developing features of this syndrome. Diagnostic requirements for PCOS are phenotypic or serologic evidence for hyperandrogenism and anovulatory cycles. Phenotypic signs of hyperandrogenism include hirsutism, truncal obesity, and acne. Hirsutism presents as increased facial and body hair, coarsening of pubic hair with extension down the inner thigh, and male-pattern scalp hair loss—temporal recession and thinning over the crown. Health consequences of PCOS include infertility, accelerated atherosclerosis, diabetes, and endometrial carcinoma, underscoring the importance of detection and treatment. As many as 30% of cycles in women with epilepsy are anovulatory, and anovulatory cycles appear to be most frequent in women receiving valproic acid. Women with epilepsy are more likely to have polycystic-appearing ovaries, which along with hyperandrogenism occur in as many as 40% of women with epilepsy receiving valproic acid. The long-term consequences of PCOS in women with epilepsy are unknown. Data such as these suggest that epilepsy and some AEDs individually affect fertility and that these effects may be additive. This implies that optimal therapy for epilepsy will consider disease-treatment effects on reproductive health.

Sexual dysfunction affects about one-third of men and women with epilepsy. Men report low sexual desire, difficulty achieving or maintaining an erection, or delayed ejaculation. Women with epilepsy can experience painful intercourse because of vaginismus and lack of lubrication. Although there are certainly psychosocial reasons for sexual dysfunction in some people with epilepsy, physiologic causes are demonstrable in others. Physiologic causes of sexual dysfunction include disruption of brain regions controlling sexual behavior by epileptogenic discharges, abnormalities of pituitary and gonadal hormones, and side effects of AEDs.

Although no anticonvulsant drug is known to be free of teratogenic effects, the risk is low and generally less than that of uncontrolled seizures during pregnancy. The exceptions to this are valproate and topiramate, both of which are associated with increased risk of congenital malformations in prospective monotherapy studies. Valproate has also been shown to carry a dose-dependent risk of decreased IQ compared with phenytoin, carbamazepine, and lamotrigine. In all cases, the lowest effective dose should be used, and polypharmacy should be avoided LEVEL 1 [13] particularly with valproate. Women with epilepsy who have difficulty conceiving, irregular or abnormal menstrual cycles, midcycle menstrual bleeding, sexual dysfunction, obesity, or hirsutism should be referred for a reproductive endocrine evaluation. Men with sexual dysfunction or difficulty conceiving should also have an endocrine evaluation and semen analysis. All the reproductive disorders seen in people with epilepsy are potentially treatable.

Bone Health

Persons with epilepsy are at greater risk for bone disease, which typically presents as pathologic fractures. Bone biochemical abnormalities described in people with epilepsy include hypocalcemia, hypophosphatemia, elevated serum alkaline phosphatase, elevated parathyroid hormone, and reduced levels of vitamin D and its active metabolites (Pack & Morrell, 2004). The most severe bone and biochemical abnormalities are found in patients receiving AED polytherapy and in those who have taken AEDs for a longer time. Effects are more pronounced with enzyme-inducing AEDs, especially phenytoin.

SURGICAL TREATMENT

Surgery should be considered when seizures are uncontrolled by optimal medical management and when they disrupt the quality of life. Quantifying these issues, however, has defied strict definition, perhaps deservedly, because intractability is clearly more than continued seizures. Only patients know how their lives differ from what they would like them to be; the concept of *disability* includes both physical and psychological components. Some patients with refractory seizures suffer little disability; others, for whatever reason, find their lives severely compromised by infrequent attacks. Still, others have had their seizures completely cured by surgery but are still disabled and incapable of functioning productively. Determining which patients are "medically refractory" and which are "satisfactorily controlled" can always be argued in the abstract. Fortunately in practice, there is usually general agreement about which patients should be referred for surgical evaluation.

Patients are less likely to benefit from further attempts at medical treatment if seizures have not been controlled after two trials of high-dose monotherapy using two appropriate drugs and one trial of combination therapy. These therapeutic efforts can be accomplished within 1 to 2 years; the detrimental effects of continued seizures or drug toxicity warrant referral to a specialized center after that time. The chance of surgical cure varies according to location and specific surgery but may be as high as 69% (Table 61.5).

There are few blanket contraindications to epilepsy surgery today, although patients with severe concurrent medical illness and progressive neurologic syndromes are usually excluded. Some centers prefer not to operate on patients with psychosis or other serious psychiatric disorder, those older than 60 years, and those with an IQ of less than 70. Patients in these categories, however, must be considered individually. Many patients who undergo corpus callosum section for atonic seizures associated with Lennox-Gastaut syndrome have IQs less than 70. Although surgery for epilepsy is increasingly performed in children, functional resections in infancy remain controversial for several reasons: the uncertain natural history of seizures in many of these patients; the unknown effects of surgery on the immature brain; and the lack of data about long-term neurologic, behavioral, and psychological outcomes.

Because of technical advances in imaging and electrophysiologic monitoring, epilepsy surgery is no longer automatically contraindicated in patients with multifocal interictal epileptiform abnormalities or even foci near language or other eloquent cortical areas.

TABLE 61.5 Outcome After Epilepsy Surgical Procedures[a]

Procedure	Seizure Free (%)	Improved (%)	Not Improved (%)	*n*
Anterior temporal lobectomy	69	22	9	3,579
Lesionectomy	67	22	12	293
Nonlesional extra-temporal neocortical resection	45	35	20	805
Hemispherectomy	67	21	12	190
Corpus callosum section	8	61	31	563

[a]Modified from Engel J Jr. *Surgical Treatment of the Epilepsies*. 2nd ed. New York, NY: Raven; 1993.

Resective Procedures

Focal brain resection is the most common type of epilepsy surgery. Resection is appropriate if seizures begin in an identifiable and restricted cortical area, if the surgical excision will encompass all or most of the epileptogenic tissue, and if the resection will not impair neurologic function. These criteria are met most often by patients with temporal lobe epilepsy, but extratemporal resections can also result in substantial benefit. The likelihood of complete seizure freedom varies somewhat by procedure; however, it is nearly always higher than with subsequent anticonvulsant trials. Very long-term outcome studies show some seizure recurrence, but most patients either have rare seizures or regain seizure freedom.

Anterior Temporal Lobe Resection

This resective procedure is the most common, but the operation varies in what is considered "standard," especially with regard to how much lateral neocortical and mesial limbic structures are removed. The traditional operation is Spencer's 1991 anteromedial temporal lobe resection, which includes removal of the anterior middle and inferior temporal gyri, parahippocampal gyrus, 3.5 to 4 cm of hippocampus, and a variable amount of amygdala. For nondominant foci, this approach may be slightly modified to include the anterior superior temporal gyrus as well. Patients with medial temporal lobe epilepsy associated with hippocampal sclerosis are ideal candidates because up to 80%

will become seizure free, with the remainder having substantial improvement. Results of a large multicenter study in the United States were reported by Spencer et al in 2003, confirming the high rates of complete seizure control following temporal lobe resection LEVEL 1.[11] A randomized controlled Canadian trial has demonstrated clear superiority of surgery over medical management in patients with medial temporal lobe epilepsy LEVEL 1.[12] Other methods of mesial temporal ablation have been reported, including Gamma Knife radiation and localized laser ablation. Overall, it is not clear if laser ablation is as efficatious for mesial temporal onset seizures as more traditional resection, however recovery time is much less, and there may be improved neuropsychological outcome as far less brain tissue is removed. If incompletely effective, a larger open resection could subsequently be performed.

Lesionectomy

Well-circumscribed epileptogenic structural lesions (cavernous angiomas, hamartomas, gangliogliomas, and mesial temporal sclerosis) can be removed by surgical resection or stereotactic laser ablation. The extent to which tissue margins surrounding the lesion are included in the resection depends on how the margins are defined (radiologic, visual, electrophysiologic, or histologic inspection) and the surgeon's preference. Seizures are controlled by this method in 50% to 60% of patients. A lesion involving the cerebral cortex should always be considered as the source of a patient's seizures, however for surgical treatment it must be supported by EEG (ictal and/or interictal, invasive when required).

Nonlesional Cortical Resections

When a lesion cannot be visualized by MRI, it is difficult to demonstrate a restricted ictal-onset zone outside the anterior temporal lobe. Although alternative imaging (PET or SPECT scan) may help identify the seizure-onset zone, this situation almost always requires placement of intracranial electrodes to map the extent of epileptogenic tissue and to determine its relation to functional brain areas. Outcome after nonlesional cortical resections is not as good as with anterior temporal lobectomy or lesionectomy, mainly because the boundaries of epileptogenic cortical areas often cannot be delineated precisely, and removal of all the epileptogenic tissue often is not possible.

Corpus Callosotomy

Section of the corpus callosum disconnects the two hemispheres and is indicated for treatment of patients with uncontrolled atonic or tonic seizures in the absence of an identifiable focus suitable for resection. Leaving the posterior 20% to 30% of the corpus callosum intact seems to reduce complications. Most patients referred for corpus callosotomy have severe and frequent seizures of multiple types, usually with mental retardation and a severely abnormal EEG (the Lennox-Gastaut syndrome).

Unlike resective surgery, corpus callosotomy is palliative, not curative. Nonetheless, it can be strikingly effective for generalized seizures, with 80% of patients experiencing complete or nearly complete cessation of atonic, tonic, and tonic-clonic attacks. This outcome is often remarkably beneficial because it eliminates falls and the associated self-injury. The effect on focal seizures, however, is inconsistent and unpredictable. Focal unaware seizures are reduced or eliminated in about half the patients, but seizures are exacerbated in about 25%. Therefore, refractory focal seizures alone are not an indication for corpus callosotomy. Similarly, absence, atypical absence, and myoclonic seizures either do not benefit or show an inconsistent response.

Hemispherectomy

Removal (hemispherectomy) or disconnection (functional hemispherectomy) of large cortical areas from one side of the brain is indicated when the epileptogenic lesion involves most or all of one hemisphere. Because hemispherectomy guarantees permanent hemiplegia, hemisensory loss, and usually hemianopia, it can be considered only in children with a unilateral structural lesion that has already resulted in those abnormalities and who have refractory unilateral seizures. Examples of conditions suitable for hemispherectomy include infantile hemiplegia syndromes, Sturge-Weber disease, Rasmussen syndrome, and severe unilateral developmental anomalies, such as hemimegalencephaly. In appropriate patients, the results are dramatic. Seizures cease, behavior improves, and development accelerates (see **Table 61.5**).

Preoperative Evaluation

The objective in evaluating patients for focal resection is to demonstrate that all seizures originate in a limited cortical area that can be removed safely. This determination requires more extensive evaluation than is necessary in the routine management of patients with epilepsy. The different tests used provide complementary information about normal and epileptic brain functions.

Video-EEG monitoring is necessary to record a representative sample of the patient's typical seizures to confirm the diagnosis and classification and also to localize the cortical area involved in ictal onset. Volumetric or other special MRI techniques may demonstrate unilateral hippocampal atrophy or other anatomic abnormalities that may be epileptogenic. The PET and ictal SPECT are useful in demonstrating focal abnormalities in glucose metabolism or cerebral blood flow that correspond to the epileptogenic brain region. Neuropsychological testing is useful in demonstrating focal cognitive dysfunction, especially language and memory. Intracarotid injection of amobarbital (the *Wada test*) to determine hemispheric dominance for language and memory competence is often necessary before temporal lobectomy (particularly involving a dominant or possibly dominant hemisphere), and mesial resection is typically not done if the remaining hemisphere has insufficient memory function. Although functional MRI reliably lateralizes language, determining memory competence of one temporal lobe has not yet been reliably established. Magnetoencephalogram (MEG) is an advanced non-invasive method of recording epileptic activity using magnetic fields produced by the flow of electrical current from epileptic cortex. This form of testing is used where other pre-surgical data are not helpful in localizing the epileptogenic zone, if the hypothesis about the epileptogenic zone is ambiguous, or if there is a paucity of interictal or ictal abnormalities on scalp EEG. It can also be used as a functional imaging test to map vital functions such as language, somatosensory and motor areas of the brain.

If noninvasive methods do not unequivocally localize the epileptogenic area, or if different noninvasive tests yield conflicting results, recording of seizures using intracranial electrodes is necessary before a definitive recommendation on surgical treatment. Intracranial electrode placement is also necessary when vital brain functions (language, motor cortex) must be mapped in relation to the planned resection. Two approaches are used

FIGURE 61.4 Position of stereotactic electroencephalogram electrodes in 51-year-old woman with refractory left temporal onset epilepsy, nonlesional (with brain lab left is left, reversed compared to magnetic resonance imaging). Electrodes of onset are circled. Bottom, electrographic onset. She became seizure free after laser ablation. Seizure onset in hippocampal head, body, and tail *(arrows)*.

with differing advantages and disadvantages. Stereotactically placed electrodes (stereo-EEG) allows the placement of multiple depth electrodes through small holes in the skull under MRI guidance. Deep structures (such as mesial temporal and insular) are more easily reached using this method, and targeting of specific lesions such as heterotopias is possible. Patients tolerate this well because no craniotomy is performed. Because each electrode pierces the cortex, however, there are relatively few contacts with the cortical surface, and mapping of eloquent cortex is limited (Fig. 61.4). Alternatively, grid and/or strips of electrodes can be placed directly on the cortical surface facilitating detailed mapping of both the seizure onset zone and eloquent cortex (Fig. 61.5). This does require a craniotomy and reasonable confidence in the zone of onset because extensive or bilateral implantation of grid electrodes carries greater risk of complications.

Neurostimulation in Drug-Resistant Epilepsy

When epilepsy surgery is not possible due to multiple foci of seizure onset or seizure onset in eloquent cortex that is not resectable, neurostimulation has emerged as an alternative to failed drug therapy.

Vagus Nerve Stimulation

The vagus nerve stimulator is an FDA-approved device for the treatment of medically refractory partial seizures. Like corpus callosotomy, vagus nerve stimulation (VNS) is a palliative procedure because very few patients become seizure free. The VNS is delivered via a stimulating lead attached to the left vagus nerve. The stimulus generator is implanted in the upper left chest. The device is usually programmed to give a 30-second electrical pulse every 5 minutes, although stimulus parameters can be adjusted to the requirements of an individual patient. In patients with aura, a magnetic wand can be used to deliver VNS on demand, which may abort seizure progression. About 55% of children have at least a 50% reduction in seizure frequency, which is comparable to the efficacy of new AEDs LEVEL 1.[13] In addition to stimulation on demand, newer models can be programmed to stimulate with increased heart rate (because this may be a signal of seizures onset); neither of these features has been subjected to randomized trials proving increased efficacy compared to standard VNS therapy. The VNS may be considered for seizures in children, for Lennox-Gastaut–associated seizures, and for improving mood in adults with epilepsy (Level C). The VNS may be considered to have improved efficacy over time. Children should be carefully monitored for site infection after VNS implantation. Chronic

FIGURE 61.5 Intracranial grid implantation in a 29-year-old man with refractory focal epilepsy. Seizure onset maps to the electrode strip in the left anterior frontal region; this is distant from eloquent cortex demonstrated by cortical stimulation mapping.

adverse effects include hoarseness and difficulty swallowing, both of which increase at the time of stimulation.

Deep Brain Stimulation

Deep brain stimulation became FDA approved in 2018 for the add-on treatment of drug-resistant focal epilepsy in adults 18 years of age and older. The anterior nucleus of the thalamus, a core component of the Papez circuit, serves as a relay station that can amplify and synchronize seizure discharges from the hippocampus and the thalamus. Therefore, its inhibition by electrical stimulation is thought to abort or prevent seizures. Multicontact depth electrodes are implanted bilaterally into the anterior nuclei using a stereotactic approach. In the pivotal deep brain stimulation study, active stimulation was associated with a 40% decrease in seizure frequency compared with 14% reduction in the control (unstimulated) group. Depression (14.8% in active treatment vs 1.8% in controls) and memory impairment (13% in active treatment vs 1.8% in controls) were the most common adverse events. Asymptomatic hemorrhages occurred in 4.5% of subjects, but no disability or death was attributed to the hemorrhages. With long-term (open-label) follow-up, median seizure reduction at 5 years was 68% with 16% of subjects seizure free for at least 6 months.

Responsive Neurostimulation

The responsive neurostimulation system is FDA approved for individuals 18 years of age or older with drug-resistant epilepsy and partial-onset seizures that localize to no more than two epileptogenic foci. The NeuroPace device consists of a pulse generator, seizure detection software, and recording and stimulating intracranial electrodes. The intracranial electrodes may be depth or subdural strip electrodes and are placed at the seizure focus that is predetermined by surface/depth video EEG evaluation. Unlike the other systems described earlier which deliver a preprogrammed stimulation to prevent seizures, the responsive neurostimulation system continuously senses electrocorticographic activity at the seizure focus and responds with stimulation only when epileptiform activity is detected, with the aim of terminating the electrical component of the seizure at its point of origin. Responsive neurostimulation is tailored by the physician for each patient, according to the patient's report of their clinical response, as well as quantitative electrocorticographic data that the device provides. There may also be neuromodulatory effects of recurrent stimulation. The physician programs the stimulation pathway and the stimulation frequency, current, pulse width, and burst duration. The most common stimulation settings in the clinical trials were 100 to 200 Hz stimulation

frequency, 1.5 to 3 mA current, 160 μs pulse width, and 100 to 200 ms burst duration. In the pivotal trial which was randomized, prospective, double-blind, sham stimulation controlled, there was no difference in the rate of adverse events between the active and sham stimulation groups. However, the study demonstrated that patients with the device turned on had a 38% reduction in the average number of seizures per month, compared to a 17% reduction in the sham group. Long-term studies suggest further improvement over time, with median seizure reduction of 75% by year 9 and 19% with a seizure free period of at least 1 year.

Once the device is implanted, patients cannot have electroconvulsive therapy, transcranial magnetic stimulation, and diathermy procedures.

Status epilepticus is covered in Chapter 7.

PSYCHOSOCIAL AND PSYCHIATRIC ISSUES

The impact of epilepsy on the quality of life is usually greater than the limitations imposed by the seizures themselves. The diagnosis of epilepsy frequently carries other consequences that can greatly alter the lives of many patients. For adults, the most important problems are discrimination at work and driving restrictions, which lead to loss of mobility and independence. Children and adults alike may be shunned by uninformed friends. Patients must learn to avoid situations that precipitate seizures, and a change in lifestyle may be necessary. Common factors that increase the likelihood of seizure occurrence include sleep deprivation (whether due to lifestyle or to coexisting sleep disorders), alcohol (and other drugs), and emotional stress (**Table 61.6**). Compliance with AED treatment is often an issue, especially with adolescents. Psychiatric symptoms, especially depression, may complicate management.

Some restrictions are medically appropriate, at least for limited times. For example, when seizures impair consciousness or judgment, driving and certain kinds of employment (working at exposed heights or with power equipment) and a few other activities (swimming alone) should be avoided. On the other hand, legal prohibitions on driving vary in different states in the United States and in different countries and are often not medically justified. Employers frequently have unrealistic fears about the physical effects of a seizure, the potential for liability, and the impact on insurance costs. In fact, the Americans with Disabilities Act prohibits denying employment to persons with disability if the disability does not prevent them from meeting job requirements.

TABLE 61.6 Factors That Lower the Seizure Threshold

Common	Occasional
Sleep deprivation	Barbiturate/benzodiazepine withdrawal
Alcohol withdrawal	Hyperventilation (absence seizures)
Stress	Flashing lights (only photosensitive patients)
Dehydration	Diet and missed meals
Drugs and drug interactions	Specific "reflex" triggers
Systemic infection	
Trauma	
Malnutrition	
Noncompliance	

Children have special problems because their seizures affect the entire family. Parents may, with the best of intentions, handicap the child by being overly restrictive. The necessary and special attention received by the "sick" child may encourage passive manipulative behavior and overdependence while unintentionally exacerbating normal sibling rivalries.

The physician must be sensitive to these important quality of life concerns, even when they are not raised spontaneously by the patient or family. In fact, psychosocial issues often become the major focus of follow-up visits after the diagnosis has been made, the initial evaluation completed, and treatment started. We cannot emphasize too much the physician's responsibility to educate society to counter misperceptions and prejudices and to separate myth from medical fact. The Epilepsy Foundation (Landover, MD; www.epilepsy.com) and its nationwide system of affiliates have a wealth of materials about epilepsy suitable for patient, family, and public education.

Depression is common in people with epilepsy: Over half of patients with uncontrolled seizures are depressed. Even patients with well-controlled seizures have higher rates of depression than the general population. Suicide rates are tripled, with the highest rates seen in the 6 months after diagnosis. Patients should be observed for signs of depression and queried specifically about their mood, with attention to the potential need for psychiatric referral and initiation of antidepressant drugs. A simple screening tool developed specifically for use in people with epilepsy appears to allow rapid and accurate recognition of major depression. The FDA released an advisory indicating an increased risk of suicidal thoughts in patients enrolled in clinical trials (0.43% in patients adding any additional agent vs 0.22% for those adding placebo). Subsequent investigations suggest that increased suicidal ideation actually precedes AED prescription, suggesting that the AEDs do not exacerbate suicidality. Regardless, it is prudent to always consider depression particularly in newly diagnosed epilepsy patients.

Treatment of depression begins with optimal treatment of the seizure disorder. Barbiturate and succinimide drugs may adversely affect mood, inducing symptoms that mimic endogenous depression. Topiramate and levetiracetam seem to cause depression in a small minority of patients, whereas lamotrigine can occasionally improve depression. Levetiracetam and perampanel have also been associated with rare psychosis. Bupropion may lower the seizure threshold and is not a treatment of choice in patients with a diagnosis of epilepsy. Although tricyclic antidepressants reduce the seizure threshold in experimental models of epilepsy, this is not a practical concern because they only rarely trigger seizures or increase seizure frequency in humans. Monoamine oxidase inhibitors neither induce seizures nor increase seizure frequency. Modern electroconvulsive therapy does not worsen epilepsy. We have used all available selective serotonin reuptake inhibitors without exacerbating seizures.

Anxiety disorders are also common in epilepsy patients. When present, some AEDs can exacerbate the condition, mainly levetiracetam, topiramate, and zonisamide. Other agents (including gabapentin, pregabalin, and benzodiazepines) can improve anxiety. Of the benzodiazepines, only clonazepam and clobazam are used for chronic treatment of epilepsy.

The relation between psychosis and epilepsy is controversial. No convincing evidence shows that interictal psychosis is

a manifestation of epilepsy, but some demographic features are overrepresented in patients with epilepsy. Postictal psychosis is, however, a well-recognized and self-limited complication of epilepsy. Its cause is unknown, but it may represent a behavioral analog of Todd paresis. Symptoms typically appear 24 to 72 hours after a lucid interval following a prolonged seizure or cluster of seizures and are more common in patients with a history of encephalitis or a family history of neuropsychiatric problems. Postictal psychosis is more common with ambiguous localization on monitoring suggesting that broad, bilaterally distributed epileptogenic networks may be a risk factor. Delusions and paranoia are common. The psychosis is self-limited, usually to a few days, although symptoms occasionally last as long as 1 to 2 weeks. Treatment with haloperidol or risperidone is usually effective. In cases where postictal psychosis regularly follows clusters of seizures, chronic treatment with low-dose risperidone can be helpful. Long-term emphasis should be on improving seizure control. Phenothiazines, butyrophenones, and clozapine lower seizure threshold in experimental animals and occasionally seem to induce seizures in nonepileptic patients. Most occurrences have been associated with high drug doses or a rapid increase in dose. With the possible exception of clozapine, however, little evidence supports the notion that reasonable and conservative use of antipsychotic medications increases seizure frequency in patients with epilepsy.

Interictal aggressive behavior is not more common in people with epilepsy. Directed aggression during seizures occurs in less than 0.02% of patients with severe epilepsy; it is almost certainly less common in the general epilepsy population. Undirected pushing or resistance occasionally occur postictally when attempts are made to restrain confused patients.

Sudden Unexpected Death in Epilepsy

Patients with epilepsy overall are at a higher risk for unexpected death compared to the general population. This is particularly devastating as it can occur in otherwise young, healthy individuals. Death can be related to injury from seizures, status epilepticus, or suicide; however, the most common cause is sudden unexpected death in epilepsy (SUDEP), occurring at a rate of at least 0.35 per 1000 person-years, although other estimates are much higher. In candidates for epilepsy surgery, the risk is estimated at up to 9 per 1000 person-years. This is a standardized mortality ratio of at least 24 times that of the general population. The SUDEP rate peaks in young adulthood, however, may be underestimated in older individuals when sudden death may be attributed to other causes.

SUDEP is generally defined as sudden, unexpected, witnessed or unwitnessed death of people with epilepsy, with or without evidence of a preceding seizure, and not due to drowning or trauma. Increased risk is most strongly associated with uncontrolled generalized convulsions. This risk is yet another reason favoring aggressive treatment toward seizure freedom in all patients, particularly from convulsive seizures. Other associated risk factors include male sex, early-onset epilepsy, nocturnal seizures, sleeping alone, and intellectual disability. Some advocate use of smart watches to alert caregivers to unrecognized convulsions; however, it is not known whether these will reduce risk of SUDEP.

Compliance

The most common cause of breakthrough seizures is noncompliance with the prescribed therapeutic regimen. Only about 70% of patients take antiepileptic medications as prescribed. For phenytoin or carbamazepine, noncompliance can be inferred when sequential blood levels vary by more than 20%, assuming similarly timed samples and unchanged dosage. Persistently low AED levels in the face of increasing dosage also generally imply poor compliance. Caution is warranted with phenytoin, however, because as many as 20% of patients have low levels as a result of poor absorption or rapid metabolism.

Noncompliance is especially common in adolescents and elderly persons, when seizures are infrequent or not perceived as disabling, when AEDs must be taken several times each day, and when toxic effects persist. Compliance can be improved by patient education, by simplifying drug regimens (using less frequent dosing with extended-release preparations when appropriate), and by tailoring dosing schedules to the patient's daily routines. Pillbox devices that alert the patient to scheduled doses can be useful. When levels are inexplicably changed in patients who insist on compliance, variability in absorption (due to change in manufacturer or gastric motility) should be considered.

Psychogenic Seizures

Psychogenic nonepileptic seizures (PNES) are diagnosed in 20% to 30% of patients who present to epilepsy centers for difficult to control seizures. They are often misdiagnosed as epileptic seizures and are treated with antiseizure medications without adequate investigation, quite often resulting in significant morbidity. The estimates of prevalence of concurrent epilepsy among patients with PNES vary from 5% to 56%. PNES are believed to be a manifestation of an underlying psychological stress and are classified under conversion disorders, which are a type of somatoform disorder. A specific traumatic event at any point of time in the patient's life, including physical or sexual abuse, death of a loved one, divorce, or other similar loss may be identified in patients with PNES. The diagnosis of PNES can be challenging because the presentation of these seizures is very diverse; they can range from mimicking a generalized convulsion to less often an atonic event. Although no single semiologic feature is specific for diagnosing PNES, the motor manifestations usually are more asynchronous, variable, and fluctuating in intensity, and specific movements such as writhing, thrashing, pelvic thrusting, and opisthotonus are more suggestive of PNES (▶ Video 61.1). Ictal stuttering, weeping, and forced eye closure are relatively uncommon in epileptic seizures and are suggestive of, but not diagnostic of, PNES. In one study, the occurrence of an episode in the doctor's examination room was estimated to have a 75% predictive value for PNES. Video-EEG evaluation is almost always required to verify the diagnosis because descriptions of patients and onlookers are invariably incomplete and even trained medical personnel cannot reliably distinguish epileptic from nonepileptic seizures by visualization alone. The PNES also can occur in patients with concurrent epilepsy, further confounding accurate diagnosis of each event. Even with video-EEG recording, some frontal lobe seizures with bizarre semiologies can be misdiagnosed as PNES and often do not have an ictal EEG correlate. The key challenge is in presenting the diagnosis to patients because acceptance of the diagnosis is a very important factor in response to treatment and counseling. Psychiatric intervention is the mainstay of treating PNES and is individualized according to the underlying psychiatric comorbidity. Ideally after diagnosis, the patients should be followed by a neurologist and a psychiatrist with close dialogue between the two, and cautious decrease or discontinuation of the antiseizure medication should

be coordinated, where applicable. Neurologic follow-up should be maintained after the diagnosis, until the patient has been fully transitioned to psychiatric care.

62 Ménière Syndrome, Benign Paroxysmal Positional Vertigo, and Vestibular Neuritis

Ian S. Storper

KEY POINTS

1. Symptoms of Ménière disease include episodic hearing loss, tinnitus, vertigo, and/or aural fullness; not all patients get all symptoms.
2. Treatment of Ménière disease is tailored to the patient and can include low-sodium diet, diuretics, corticosteroid therapy, intratympanic gentamicin, and surgery.
3. Benign paroxysmal positional vertigo is characterized by episodic short-lived episodes of vertigo that occur with positional changes. Diagnosis is established by history and positive Dix-Hallpike maneuver. Usual treatment is by canalith repositioning maneuvers on a patient who can tolerate them.
4. Vestibular neuritis typically causes severe vertigo of sudden onset, which improves over days to weeks.
5. It is important to rule out central processes when the diagnosis is not absolutely clear.

INTRODUCTION

Three of the most common causes of peripheral vertigo are Ménière syndrome, benign paroxysmal positional vertigo (BPPV), and vestibular neuritis. Each syndrome has its own distinct type of vertigo. The purpose of this chapter is to explain the clinical presentation and current treatment principles of each syndrome to aid the clinician in diagnosis and management.

MÉNIÈRE DISEASE

Although Ménière disease was described over 140 years ago, little about it is understood. The condition is often progressive; with medical and surgical treatment options, however, disability may be averted or ameliorated. A recent study using health claims data from 60 million patients in the United States reports prevalence as 190 per 100,000 with a female-to-male ratio of 1.89:1. The prevalence increases with age.

This disease was first reported by Prosper Ménière in Paris in 1861. As described, patients typically suffered recurrent attacks of vertigo lasting from hours to days. Coincident with the attacks were episodes of unilateral hearing loss and roaring tinnitus. At first, the hearing loss and tinnitus occurred only with the attacks, but as the disease progressed, they became permanent. In 1943, Cawthorne added a fourth symptom: fullness in the affected ear. Table 62.1 lists the clinical features of Ménière disease. Although the cause of Ménière disease still remains unknown, it was postulated by Knapp in 1871 that symptoms were caused by dilatation of the endolymphatic compartment of the inner ear during attacks and renormalization afterward. This idea is still widely accepted because the vast majority of patients respond to sodium management.

TABLE 62.1 Ménière Disease Clinical Features

Episodes of the following:
• Unilateral hearing loss
• Tinnitus in affected ear
• Vertigo
• Fullness in affected ear

Definitions

Ménière disease is defined as the *idiopathic* occurrence of attacks of vertigo, hearing loss, tinnitus, or fullness in the affected ear. If a cause is assumed, the term is *Ménière syndrome*. The causes of Ménière syndrome are listed in Table 62.2.

Episodes typically last from hours to days. After an attack, the patient often feels "foggy" or tired. Initially, only one or two symptoms may be present, for example, a patient may experience only episodic vertigo; the hallmark is fluctuation. In the early stages, patients are often asymptomatic between attacks. With progression, low-frequency hearing loss can become permanent and may progress to all frequencies. Tinnitus is usually loud and roaring. Vertigo can be severe, a true spinning sensation of the patient or surroundings. Nausea, vomiting, sweating, and pallor are typical because the vertigo arises in the inner ear rather than in the brain. Some describe a linear motion or feel as if they are on a boat. Rarely, vertigo is noted only with change of position, mimicking BPPV. It is distinguishable because positional vertigo of Ménière disease occurs in attacks.

TABLE 62.2 Some Causes of Ménière Syndrome

• Trauma of the inner ear or rupture of the inner ear membranes
• Postinfectious: labyrinthitis, meningitis, Lyme disease, or otosyphilis
• Congenital anatomic abnormality
• Tumor, for example, vestibular Schwannoma pressing on the eighth nerves
• Vertebrobasilar insufficiency—central signs and symptoms are also seen

If left untreated, disequilibrium may persist between attacks of vertigo. More than half of Ménière sufferers are women, a fact possibly a ributable to hormonal causes of increased water retention. Symptoms may be worse prior to the menstrual cycle.

Typically, attacks become less frequent and less severe over time, with or without medical management. Within about 2 years of diagnosis, more than half of all patients are better, even without treatment. Treatment decreases the frequency and severity of attacks and minimizes permanent hearing or balance loss. Only 5% of medically treated patients progress to surgery.

About 10% of patients never experience vertigo; their disorder is termed *cochlear Ménière disease*. Ten percent of patients never experience auditory symptoms. The term *burned out Ménière disease* applies to the patient who has totally lost auditory and vestibular function. There is no loss of consciousness during Ménière attacks; if it occurs, neurologic disease is likely. A rare entity associated with Ménière disease is referred to as *drop attack* or *crisis of Tumarkin*, where the patient suddenly drops to the ground. Head injury may ensue.

Diagnosis

Ménière disease is diagnosed clinically; no test has sufficient sensitivity and specificity to be pathognomonic. Tests are used to rule out other disorders and to help confirm the diagnosis. Careful history and physical examination are essential. Ménière disease should be considered in any patient without other obvious cause who suffers episodic vertigo, hearing loss, tinnitus, or fullness in the ear. Ménière disease is not diagnosed unless symptoms have occurred at least twice. Between attacks, the examination is often normal, especially early in the disease. During an attack, a patient typically appears acutely vertiginous, with horizontal nystagmus beating toward the affected ear. If nystagmus is vertical, central nervous system disease is considered.

Tests that aid in the diagnosis of Ménière disease include audiometry (complete audiologic evaluation), videonystagmography, and magnetic resonance imaging (MRI). If the symptoms are bilateral, blood tests for autoimmune inner ear disease and infections are ordered. Early in the disease, the complete audiologic evaluation is often normal. Later, low-frequency sensorineural hearing loss can develop. Ultimately, hearing loss may also involve high frequencies. Rarely, the hearing asymmetries may be in the high frequencies rather than the low frequencies. During an attack, there may be hearing loss in the affected ear, which may resolve afterward. If conductive hearing loss is found, other diagnoses, such as superior semicircular canal dehiscence or cholesteatoma, should be considered.

Early in Ménière disease, the videonystagmography is usually normal because vestibular function recovers between attacks. As the disease progresses, caloric testing often yields a unilateral vestibular weakness. If testing is inadvertently performed during an attack, hyperfunction of the affected ear is usually seen. In end-stage disease, there is complete weakness (100%) in the affected ear. If central pathology is the cause of vertigo, caloric test results are usually normal. Gaze and positional testing, as well as optokinetic nystagmus testing, are often abnormal.

MRI is recommended for every patient with recurrent vertigo, asymmetric sensorineural hearing loss, or unilateral constant tinnitus. The study should include the brain and internal auditory canals, with and without gadolinium. This test evaluates intracranial pathology such as vestibular Schwannoma, stroke, or demyelination, which can cause these symptoms. If symptoms begin after age 60 years, Doppler examinations are performed to evaluate possible cerebrovascular disease. Electrocochleography is helpful in diagnosing Ménière disease. The test demonstrates high ratios of the summating potential/action potential in Ménière patients; sensitivity and specificity are not high enough for routine use. Once other causes are excluded, the most accurate way to establish the diagnosis is to determine whether it responds to treatment.

Medical Treatment

Therapy begins with diet and medication. Approximately 85% of patients respond very well, with significant decrease in frequency and severity of attacks. About 5% of patients find that therapy with diet and medication is inadequate and requires middle ear injections or surgery.

The standard for medical management is a low-sodium diet and thiazide diuretic. First, it should be ascertained that this is safe for the patient by consultation with their internist. A new patient should be started on a diuretic between attacks of vertigo. Diet should be a strict 1,500 mg/d sodium regimen; the patient should be informed that this requires checking labels carefully. If patients eat outside the home, it should be in places where they can limit the amount of sodium. Sodium intake should be even with each meal to avoid surges in pressure. Patients are advised to drink copious amounts of water to help flush out the sodium and maintain blood pressure. They are urged to avoid caffeine and alcohol, which are thought to aggravate symptoms. Emotional stress can also aggravate Ménière disease, and psychiatric consultation may be necessary.

Because sodium levels are hormonally regulated, adding a diuretic is useful. Typically, the patient is started on hydrochlorothiazide 37.5 mg/triamterene 25 mg once daily. This diuretic sheds sodium well and is required only once daily. Triamterene typically protects the potassium level. Electrolyte levels and renal function should be monitored periodically while this diuretic is being taken. Discontinuation or dose adjustment may be required. Patients should be advised that it can take a few weeks to know if this regimen is beneficial.

Vestibular suppressants can help control vertigo during attacks. Anticholinergic drugs are useful because they are not severely sedating. The author prefers glycopyrrolate 2 mg orally twice daily as needed during attacks. An alternative is meclizine 12.5, 25, or 50 mg orally up to 3 times daily. Although meclizine is effective, it is sedating. Benzodiazepines are also vestibular suppressants. Diazepam 5 mg orally 3 times daily during attacks can be useful but is also sedating and habit-forming. It should be used with caution if vertigo does not respond to the other drugs mentioned. Corticosteroids may also be beneficial. Table 62.3 summarizes medical treatment of Ménière disease.

TABLE 62.3 Medical Treatment of Ménière Disease

• 1,500 mg/d sodium diet and increased water intake
• Thiazide diuretic
• Vestibular suppressants
• Anticholinergics
• Antihistamines
• Benzodiazepines
• Corticosteroids

In the event of intractable vertigo with nausea and vomiting, an emergency room visit may be necessary. Intravenous hydration should be administered, being careful not to overload the patient with sodium. Promethazine 75 mg intramuscularly or droperidol 0.625 mg intravenously are useful for emergencies, but both are heavily sedating.

Surgical Management

Surgical treatments for Ménière disease may be destructive or conservative. In all cases, these operations are performed only if symptoms persist despite medical optimization.

Conservative Procedures

Endolymphatic Shunt

These procedures are designed to decrease the pressure in the endolymphatic compartment by shunting the fluid out of it. Current shunting procedures are performed under general anesthesia by drilling medially through the mastoid cortex down to the endolymphatic sac, opening it, and allowing the fluid to drain into the mastoid cavity.

In the past, shunts were controversial. The controversy arose in the 1980s when a Danish group found similar vertigo control in patients who had undergone endolymphatic shunts to those who had undergone only mastoidectomy ("sham procedures"). However, the same data were reevaluated in 2000 by Welling and Nagaraja LEVEL 1.[1] In comparing the shunt group to the sham group, vertigo control was significantly better in the shunt group, nausea and vomiting were significantly less in the shunt group, and tinnitus was significantly less in the shunt group. Sood et al in 2014 published a meta-analysis of all articles citing results from this operation according to current guidelines from 1970 to 2013. They report that endolymphatic shunt controls vertigo effectively in 75% of patients who failed medical treatment LEVEL 3.[2] Complications of shunt procedures are rare and do not differ significantly from those of mastoidectomy. It is a reasonable first procedure for patients with good hearing and mild to moderate vertigo.

Vestibular Neurectomy

The vestibular nerve can be separated from the cochlear nerve and sectioned. Although the vestibular nerve is cut, this procedure is generally considered a conservative procedure because hearing is preserved. The risks of craniotomy must be considered, and the indications are more stringent. Patient selection criteria for vestibular neurectomy include episodic disabling vertigo owing to Ménière disease, serviceable hearing in the affected ear, and failure of medical management. Moreover, there must be unilateral vestibular weakness in the affected ear on caloric testing but not 100%. This procedure should not be performed on the side of an only hearing or significantly better hearing ear. The results of vestibular neurectomy are excellent. Vertigo is controlled in 94% of patients. Hearing loss, tinnitus, and fullness are unaffected; the patient must continue on low-sodium diet and diuretic. Complications include sensorineural hearing loss in 2% to 3% of patients, cerebrospinal fluid leak in 5% to 12%, temporary unsteadiness in up to 25%, headache in 10%, and tinnitus in 7%. As intratympanic gentamicin injection theoretically provides a similar result without having to undergo craniotomy (see text which follows), it is often tried prior to vestibular neurectomy. Vestibular neurectomy should be performed in patients with disabling episodic vertigo or in those who have failed shunt surgery and/or intratympanic gentamicin treatment.

TABLE 62.4 Surgical Options for Ménière Disease

• Endolymphatic shunt
• Vestibular neurectomy
• Labyrinthectomy

Destructive Procedures Labyrinthectomy

In this operation, the vestibular portion of the inner ear is destroyed and all five end organs are removed. Because the hearing in the operated ear is destroyed, this procedure is limited to patients with no serviceable hearing in the affected ear; who suffer from episodic, disabling vertigo; and in whom medical management has failed. This is the standard for vertigo control in patients with no hearing. Vestibular weakness must be shown in the affected ear on caloric testing but not 100%. Labyrinthectomy typically eradicates attacks of vertigo about 95% of the time. Aside from temporary postoperative unsteadiness in 10% of patients, the risks of this procedure do not differ significantly from those of mastoidectomy. Table 62.4 lists surgical options for Ménière disease.

Other Treatment Methods

Intratympanic and Oral Corticosteroids

Intratympanic dexamethasone given at regular intervals has been described as a method of controlling episodes of Ménière disease, which continue despite adherence to low-sodium diet and diuretic therapy LEVEL 2.[3] Typically, three perfusions of dexamethasone 24 mg/mL separated by 10 minutes are performed for a total of 1 mL. Repeat injections may be necessary for recurrent symptoms. This modality may also be used for severe episodes of vertigo or hearing loss, along with or without oral corticosteroids depending on whether a patient can take them safely; consultation with an internist, endocrinologist, gastroenterologist, and/or psychiatrist is recommended if there is any question about patient safety with oral corticosteroids. In general, intratympanic doses do not cause systemic effects.

Intratympanic Gentamicin

Gentamicin is instilled into the middle ear, which provides a pathway into the inner ear via the round window. This aminoglycoside preferentially destroys vestibular hair cells over cochlear hair cells. Results vary. Vertigo control is about 80%, but there is significant incidence of sensorineural hearing loss. In one study, it was found that patients given intratympanic gentamicin had a statistically significant decrease in pure tone average and speech discrimination scores but that patients undergoing vestibular neurectomy did not. Vertigo control was achieved in 80% of patients given gentamicin and in 95% of patients with neurectomy. In another study, 90% of patients had complete initial control of vertigo after gentamicin, but 29% had recurrence after 4 months. In a third more recent study, 85% of patients had complete control of vertigo from gentamicin perfusion, but hearing was decreased in 25.6% LEVEL 2.[4-6] Gentamicin is less effective for vertigo control than surgery. There is risk of postprocedure long-term unsteadiness. In 2014, Casani et al demonstrated less long-term unsteadiness and hearing loss using a lower dose regimen. With these lower risks, because this modality does not require craniotomy, it is now often performed instead of vestibular neurectomy.

Vestibular neurectomy may still be performed in certain cases or when intratympanic gentamicin is ineffective and the patient has serviceable hearing.

Meniett Device

This device delivers pressure pulses to the inner ear via a tympanostomy tube to generate gradients in the endolymphatic compartment via the round window. The device is worn for 5 minutes 3 times per day. Significant benefit from the use of this device has not been clearly demonstrated.

Streptomycin

This drug has been banned by the U.S. Food and Drug Administration because of its inner ear toxicity. However, it is useful for end-stage patients with bilateral Ménière disease who still have attacks of vertigo and no hearing. The drug is administered intramuscularly, in regular doses, until caloric responses disappear. The drug eradicates the remaining vestibular function. Obtaining and administering this drug requires government approvals. Use of this drug has largely been replaced with intratympanic gentamicin.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

BPPV has been described as the most common cause of peripheral vertigo with prevalence from 10.7 to 64 cases per 100,000 and prevalence over a lifetime of 2.4%. The average age of onset is from 50 to 60 years, with a 2 to 3:1 female-to-male ratio. It was first described by Barany in 1921. Patients report episodic vertigo sensations, which are caused by head motion; often, patients describe it as being aggravated by arising from or getting into bed or tossing during sleep. These episodes can be intense and can cause a fall. Characteristically, there is no vertigo if there is no head motion. Each episode typically lasts for less than a minute. There is no hearing loss, tinnitus, or fullness in the ear associated with this condition. The incidence increases with age and there is a slight female-to-male predominance. Approximately half of cases occur after head trauma.

This disorder is thought to be caused by dislodgment of otoconia—calcium carbonate crystals normally present in the utricle or saccule—into the semicircular canals. These crystals add inertia to the torsion-pendulum model of semicircular canal activation. When there is a mismatch of inertia between the two ears, there is disagreeing signal sent along the right and left vestibular nerves, resulting in nystagmus and a sensation of vertigo until the inner ear motion has stopped. This condition is self-limited; it, however, can be present for an extended period of time prior to dissipating. This condition most commonly occurs in the posterior semicircular canal and occasionally the horizontal semicircular canal; it rarely occurs in the superior semicircular canal.

Diagnosis is established by provocative positional maneuvers. For posterior canal BPPV, the Dix-Hallpike maneuver is performed, where the patient's head is turned toward the affected side and they lie back quickly, extending the neck. If the maneuver is positive, vertical-torsional nystagmus is seen for a number of seconds, with latency and fatigability. For horizontal canal BPPV, diagnosis is established by seeing horizontal nystagmus with latency and fatigability when rolling the head to the affected side in the supine position. Diagnosing superior canal

FIGURE 62.1 The Modified Epley maneuver. (From Mayer SA, Marshall RS, eds. Headache. In: *On Call: Neurology*. 4th ed. St. Louis, MO: Elsevier; 2020:211.)

BPPV involves eliciting vertical nystagmus and central lesions need to be excluded. These maneuvers should not be performed unless neurovascular problems have been excluded first.

Treatment involves canalith repositioning maneuvers, thought to dislodge the crystals and allow them to drop out into a safe compartment of the inner ear. Although there are numerous maneuvers, the most common ones are those described by Epley in 1992. For posterior semicircular canal BPPV, the maneuver consists of five steps: (1) Dix-Hallpike maneuver; (2) turning the head to the opposite side; (3) rolling over onto the opposite side, head downward; (4) sitting up and then turning the head forward; and (5) tucking the chin (Fig. 62.1). The maneuver is repeated until nystagmus dissipates. The patient is instructed to keep their head level for the next 48 hours. This maneuver is highly successful but sometimes has to be repeated over multiple sessions. Physical therapists can be consulted. For severe, recalcitrant cases, singular neurectomy can be offered.

VESTIBULAR NEURITIS

Vestibular neuritis (or vestibular neuronitis) was described by Dix and Hallpike in 1952. It is a clinical syndrome where a patient develops severe vertigo, often associated with nausea, vomiting, and/or prostration, which resolves over a period of

days to weeks. There are no other neurologic deficits, and there is no loss of consciousness. In general, older age portends a prolonged and possibly incomplete recovery. Vestibular neuritis has an incidence of about 3.5 cases per 100,000 persons. Typical age of onset is between 30 and 60 years, and there is no gender difference. Approximately 30% of affected individuals suffered an upper respiratory infection preceding their symptoms.

The cause of this condition has been postulated to be reactivation of herpes simplex or other neurotropic virus, but this has not been proven. Histologic findings performed postmortem on individuals who have suffered this condition have shown an atrophic superior vestibular nerve and ganglion.

Treatment is supportive. Hydration may be required, and during the intense period, vestibular suppressants are helpful. They should be discontinued as soon as reasonable as they can prolong recovery time. Imaging studies such as MRI and computed tomography angiography are typically ordered to rule out neurovascular or other central causes. Patients usually exhibit nonfatigable horizontal nystagmus at presentation. After the initial severe vertigo has dissipated, recovery time can be prolonged in some individuals whence vestibular rehabilitation can be beneficial. A recent study showed that corticosteroids administered over the first 3 weeks after onset improved symptoms more quickly than vestibular rehabilitation but that long-term results were similar LEVEL 1.[7] For patients taking a long time to recover, vestibular rehabilitation may be beneficial.

CONCLUSION

The clinical syndromes of three of the most common types of peripheral vertigo have been discussed. It should be remembered that there are numerous other causes of peripheral and central vertigo to be considered when evaluating patients.

Transient Global Amnesia 63

John C. M. Brust

KEY POINTS

1. Transient global amnesia is characterized by sudden onset of anterograde and retrograde amnesia, with gradual clearing over hours.
2. Attacks recur in a minority of patients.
3. Neither transient ischemic attack nor seizure disorder appear to be the cause in the great majority of cases.

INTRODUCTION

Transient global amnesia (TGA) is characterized by sudden inability to form new memory traces (*anterograde amnesia*) in addition to retrograde memory loss for events of the preceding days, weeks, or even years.

EPIDEMIOLOGY

Patients are usually middle aged or elderly and otherwise healthy. Recurrent attacks occur in 15% to 30% of cases, and fewer than 3% have more than three attacks. Intervals between attacks range from 1 month to 19 years.

PATHOBIOLOGY

The cause of TGA is uncertain. Case-control series and anecdotal reports variably implicate seizures, stroke, or migraine. Against an epileptic basis for TGA are the infrequency of recurrence, absence of other seizure phenomena, and normal electroencephalogram even during attacks. In transient epileptic amnesia, attacks are usually less than an hour in duration, tend to occur on awakening, are often accompanied by other ictal symptoms, and are likely to recur; ictal and interictal electroencephalogram abnormalities are often present, and symptoms respond to anticonvulsant therapy.

TGA has been anecdotally described in association with carotid artery occlusion and amaurosis fugax, with infarction of the inferomedial temporal lobe, the cingulate gyrus, or the retrosplenial corpus callosum and as a complication of cerebral angiography (especially vertebral). In large series, however, major risk factors for stroke (hypertension, diabetes mellitus, tobacco, ischemic heart disease, atrial fibrillation, and past stroke or transient ischemic attack [TIA]) are no more common among patients with TGA than in age-matched controls, and TGA is not a risk factor for stroke. The vast majority of TGA attacks last more than an hour; the vast majority of TIAs last less than an hour. Studies addressing a possible association of TGA with cardiac valvular disease or patent foramen ovale have been inconsistent. Patients with amnestic stroke owing to documented posterior cerebral artery occlusion do not report previous TGA; their neurologic signs usually include more than simple amnesia (eg, visual impairment), and they infrequently exhibit repetitive queries. Reduced blood flow to the thalamus or temporal lobes has been documented during attacks of TGA but could be secondary to neuronal dysfunction rather than its cause. TGA symptoms were reported in nine patients with aortic dissection, five of whom had no chest pain.

Valve incompetence of the internal jugular vein is present in many patients with TGA, raising the possibility of cerebral venous congestion during Valsalva-like activities. Intracranial venous reflux during Valsalva maneuver could not be demonstrated in the same patients, however, and such a mechanism is unlikely to explain symptoms that last hours and seldom recur.

Epidemiologic studies confirm an association of TGA with migraine, even though in most migraine patients, headache attacks are recurrent, whereas attacks of TGA are not. Sometimes, both amnestic and migrainous attacks (including visual symptoms and vomiting) occur simultaneously or follow one another. A case report described a man with repeated episodes of TGA associated with sexual activity whose spells cleared as long as he took the β-blocker metoprolol. Cortical spreading depression (possibly the pathophysiologic basis of cerebral symptoms of migraine) could, by affecting the hippocampus, explain some cases of TGA.

CLINICAL MANIFESTATIONS

During attacks, which affect both verbal and nonverbal memory, there is often bewilderment or anxiety and a tendency to repeat one or several questions (eg, "Where am I?"). Physical and neurologic examinations, including mental status, are otherwise normal. Immediate registration of events (eg, serial digits) is intact, and self-identification is preserved. Attacks last minutes or hours, rarely longer than a day, with gradual recovery. Retrograde amnesia clears in a forward fashion, often with permanent loss for events occurring within minutes or a few hours of the attack; there is also permanent amnesia for events during the attack itself. Headache frequently accompanies attacks; less often, there is nausea, dizziness, chills, flushing, or limb paresthesias. TGA is frequently precipitated by physical or emotional stress, such as sexual intercourse, driving an automobile, pain, photogenic events, or swimming in cold water. Because amnesia can accompany a variety of neurologic disturbances, such as head trauma, intoxication, partial complex seizures, or dissociative states, criteria for diagnosing TGA should include observation of the attack by others.

Permanently impaired memory following an acute attack is rare, although subtle defects have been reported.

FIGURE 63.1 Examples of lesions in the head, body, and tail of the hippocampus (arrows) as well as the frequency of lesion locations in the different hippocampal areas. (Reproduced with permission from Szabo K, Hoyer C, Caplan LR, et al. Diffusion-weighted MRI in transient global amnesia and its diagnostic implications. *Neurology*. 2020;95[2]:e206-e212.)

DIAGNOSIS

Diffusion-weighted magnetic resonance imaging detects highly focal lesions in the CA1 field of the hippocampus in 70% of TGA patients, bilaterally in only 12%, with maximum sensitivity 12-48 hours after TGA onset (ie, not neccessarily during the acute memory impairment) and disappearing over several weeks (Fig. 63.1). Magnetic resonance spectroscopy identified reversible lactate peaks within the same lesions, consistent with ischemia. Functional magnetic resonance imaging during the acute phase of amnesia identified reversible reduced functional connectivity bilaterally in hippocampi and other temporolimbic regions considered part of an "episodic memory network."

TREATMENT

A study of 142 cases plus literature review suggested three subgroups of TGA (excluding patients with epilepsy or TIA). In women, TGA was mainly associated with an emotional precipitating event and a history of anxiety or depression. In men, attacks are more often followed a physical precipitating event perhaps associated with a Valsalva maneuver. In younger patients, an association with migraine was most prominent. Thus, even when strict diagnostic criteria are applied, TGA probably has diverse origins. In patients in whom epilepsy and migraine can be excluded and who have risk factors for cerebrovascular disease, antiplatelet drugs should be considered, but the benign natural history makes it difficult to evaluate any preventive treatment.

Acute Bacterial Meningitis 64

Karen L. Roos

KEY POINTS

1. Acute bacterial meningitis is a purulent infection in the meninges and the subarachnoid space that is rapidly complicated by diffuse cerebral edema, increased intracranial pressure, hydrocephalus, ischemic and hemorrhagic stroke, seizures, and coma.
2. The clinical presentation of bacterial meningitis includes two or more of the following four symptoms and signs: (1) fever (≥38.5°C), (2) headache, (3) nuchal rigidity, and (4) an altered level of consciousness. A symptom that is often present, but underrecognized as a symptom of central nervous system infection, is vomiting.
3. When acute bacterial meningitis is a possibility, obtain Gram stain and blood cultures, serum procalcitonin, and C-reactive protein and begin empiric adjunctive and antimicrobial therapy. Empiric antimicrobial therapy should include therapy for viral encephalitis and a tickborne bacterial infection during the season when ticks are biting.

INTRODUCTION

Acute bacterial meningitis is a purulent infection in the meninges and the subarachnoid space that is rapidly complicated by diffuse cerebral edema, increased intracranial pressure, hydrocephalus, ischemic and hemorrhagic stroke, seizures, cerebritis, and cranial nerve palsies. The complications associated with acute bacterial meningitis make this infection distinctly different than acute viral meningitis. In the latter, infection is limited to the meninges and the subarachnoid space. Bacterial meningitis involves "more than the meninges." When the clinical presentation raises a suspicion for bacterial meningitis, empiric therapy is initiated prior to the diagnostic workup, and modified once the disease is either ruled out, or the meningeal pathogen is identified and treatment guided by antimicrobial sensitivities.

ETIOLOGY

The most common causative organisms of community-acquired bacterial meningitis are *Streptococcus pneumoniae* and *Neisseria meningitidis*.

The most important antecedent illnesses for pneumococcal meningitis are pneumonia, acute otitis media, and acute sinusitis. Whereas the pneumococcal conjugate vaccines have decreased the incidence of otitis media and bacteremia due to *S pneumoniae*, the number of serotypes of *S pneumoniae* in the vaccines is 13% of the number of serotypes of *S pneumoniae*, and the increased incidence of pneumococcal meningitis due to a serotype not in the vaccines is concerning.

In children and adolescents ages 2 to 18 years, *N meningitidis* has been the most common pathogen, but the incidence of meningitis due to this organism has decreased with the immunization of children and adolescents with the tetravalent (serogroups A, C, W-135, and Y) meningococcal vaccine. No vaccine was available in the United States for serogroup B until an outbreak of meningococcal meningitis due to serogroup B occurred at Princeton University followed by outbreaks at eight other American Universities between 2013 and 2016. Vaccination against serogroup B meningococcus (MenB vaccine) has since become a standard recommendation from the Advisory Committee on Immunization Practices as part of the compulsory vaccination schedule of many American universities and for person aged 10 years and older with complement deficiency and anatomic or functional asplenia (including sickle cell disease).

Although *S pneumoniae* and *N meningitidis* are the most common causative organisms of community-acquired meningitis, age, predisposing, and associated conditions put the individual at risk for meningitis due to other organisms (Table 64.1). In the neonatal age group, group B streptococci and *Escherichia coli* are the most common meningeal pathogens. The causative organisms of meningitis associated with otitis media, mastoiditis, or sinusitis are *Streptococci* species (including *S pneumoniae*), gram-negative anaerobes, *Staphylococcus aureus*, *Haemophilus* species, or Enterobacteriaceae. Patients with congenital or acquired deficiency in the terminal common complement pathway (C3 and C5-C9), immunoglobulin deficiency or asplenia are at risk for meningitis due to encapsulated organisms, specifically *N meningitidis* and *S pneumoniae*. Patients with meningitis due to encapsulated organisms should have diagnostic testing for deficiencies of complement or immunoglobulins and functional asplenia (ie, sickle cell disease).

Listeria monocytogenes is a causative organism of bacterial meningitis and brainstem encephalitis in individuals with impaired cell-mediated immunity from age (neonates and adults older than 50 years of age), immunosuppressive therapy, pregnancy, and chronic illness.

Meningitis complicating endocarditis may be due to viridans streptococci, *S aureus*, *Streptococcus bovis*, the HACEK group, or enterococci. The vegetation on the heart valve is a source of septic emboli to the brain. Infective endocarditis causes bacterial meningitis, brain abscess, ischemic and hemorrhagic stroke, and cerebral mycotic aneurysms.

Staphylococci, gram-negative bacilli, or anaerobes are the most common organisms causing meningitis in the postneurosurgical

TABLE 64.1 Meningeal Pathogen Based on Predisposing and Associated Conditions

Predisposing Condition	Bacterial Pathogen
Neonate	Group B streptococcus, *Escherichia coli*, *Listeria monocytogenes*
Children and adults—community acquired	*Streptococcus pneumoniae* and *Neisseria meningitidis*
Otitis, mastoiditis, sinusitis	Streptococci species (anaerobic, aerobic, and viridans) Gram-negative anaerobes (*Bacteroides* species, *Fusobacterium* species), Enterobacteriaceae (*Proteus* species, *E coli*, *Klebsiella* species, *Enterobacter* species, *Serratia* species) *Staphylococcus aureus*, *Haemophilus influenzae*
Adults older than the age of 55 and those with chronic illness	*S pneumoniae*, gram-negative bacilli, *N meningitidis*, *L monocytogenes*, *H influenzae*
Endocarditis	Viridans streptococci, *S aureus*, *Streptococcus bovis*, HACEK group,[a] Enterococci
Immunosuppressed	*S pneumoniae*, *L monocytogenes*, *H influenzae*
Postneurosurgical	Staphylococci, gram-negative bacilli
Intraventricular device	Staphylococci, gram-negative bacilli, anaerobes

[a]The HACEK group is *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

patient. Head trauma with basilar skull fracture and chronic medical conditions, such as diabetes and alcoholism, also increase the risk of meningitis.

PATHOBIOLOGY

Both *N meningitidis* and *S pneumoniae* are transmitted by aerosolized droplets of respiratory secretions and initially colonize the nasopharynx by attaching to the nasopharyngeal epithelial cells. Following colonization of the nasopharynx, the bacteria enter the bloodstream and gain access to the cerebrospinal fluid (CSF) through the choroid plexus of the lateral ventricles. Most meningeal pathogens are bloodborne organisms, with the exception of those that gain access to the subarachnoid space from a contiguous site of infection.

It is not simply the presence of bacteria in the subarachnoid space that induces the inflammatory response. Rather, the lysis of bacteria with the subsequent release of bacterial cell wall components into the subarachnoid space is the initial step in the induction of the inflammatory response and the formation of a purulent exudate in the subarachnoid space. The specific bacterial cell wall components that induce inflammation are teichoic acid, a component of the cell wall of most gram-positive bacteria, and endotoxin, a lipopolysaccharide molecule of the outer membrane of gram-negative bacteria.

Bacterial cell wall components induce meningeal inflammation by stimulating the release of the inflammatory cytokines, interleukin-1β (IL-1β), and tumor necrosis factor α (TNF-α). Both IL-1β and TNF-α are produced by monocytes and macrophages and brain astrocytes and microglial cells (central nervous system macrophage-equivalent cells) that are "activated" by exposure to lipopolysaccharide and other bacterial cell wall components. In experimental models, the intracisternal inoculation of IL-1β and TNF-α induces meningeal inflammation (neutrophil emigration into CSF) and impaired blood-brain barrier permeability in a time and dose dependent manner.

The pathophysiologic consequences that result from the presence of the inflammatory cytokines in CSF are demonstrated in **Figure 64.1**. There is an increased permeability of the blood-brain barrier that contributes to vasogenic edema and allows for the leakage of serum proteins into the subarachnoid space contributing to the formation of a purulent exudate. The purulent exudate of proteinaceous material and leukocytes that forms in the subarachnoid space obstructs the flow of CSF through the ventricular system and diminishes the resorptive capacity of the arachnoid granulations in the dural sinuses. This results in obstructive and communicating hydrocephalus and interstitial edema. The combination of vasogenic and interstitial edema leads to increased intracranial pressure and an altered level of consciousness.

The purulent exudate surrounds and narrows the diameter of the lumen of the large arteries at the base of the brain with infiltration of inflammatory cells in the arterial walls (vasculitis). The procoagulant state results in arterial and venous thrombosis. Systemic hypotension due to sepsis contributes to global cerebral hypoperfusion.

Bacteria and the inflammatory cytokines induce the production of excitatory amino acids, reactive oxygen, and nitrogen species that induce apoptosis of neurons. Neurocognitive deficits are the result of apoptosis of neurons in the dentate gyrus of the hippocampus.

Cortical inflammation, cortical ischemia, intraparenchymal hemorrhage, and cerebral edema cause epileptogenic foci. Seizures are common in bacterial meningitis. Hearing loss in bacterial meningitis is due to direct damage to the inner ear by inflammation.

CLINICAL MANIFESTATIONS

The classic triad of meningitis is fever, headache, and meningismus. The classic triad applies only to viral meningitis. The clinical presentation of bacterial meningitis includes two or more of the following four symptoms and signs: (1) fever (≥38.5°C), (2) headache, (3) nuchal rigidity, and (4) an altered level of consciousness. A symptom that is often present, but underrecognized as a symptom of central nervous system infection, is vomiting.

The classic signs of meningeal irritation are nuchal rigidity (*stiff neck*, *meningismus*), Kernig sign, and Brudzinski sign. Nuchal rigidity is present when the neck resists passive flexion. Kernig sign is typically elicited with the patient in the supine position, but the patient can be in the seated position if their level of consciousness is normal. The thigh and the knee are flexed. Passive extension of the leg elicits pain when meningeal irritation is present. Brudzinski sign is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees.

Patients with bacterial meningitis have either a fulminant illness that develops over a matter of hours or a subacute illness that progresses over 24 to 72 hours. The patient's level of consciousness may become progressively worse over a short

FIGURE 64.1 The pathophysiology of the neurologic complications of bacterial meningitis. Abbreviations: CSF, cerebrospinal fluid; SAS, subarachnoid space. (Reproduced with permission from McGraw-Hill.)

period of time. The tempo of the illness, and the time to presentation to the emergency department from the onset of illness, affects the signs and symptoms at presentation. As the disease progresses, and the complications of seizures, increased intracranial pressure, and cerebral ischemia and intracerebral hemorrhage occur, the patient's level of consciousness evolves from lethargy to stupor to obtundation to coma, and focal neurologic deficits may develop.

DIAGNOSIS

When acute bacterial meningitis is a possibility, obtain Gram stain and blood cultures, serum procalcitonin, and C-reactive protein and begin empiric adjunctive and antimicrobial therapy (Level 2). Empiric antimicrobial therapy should include therapy for viral encephalitis and a tickborne bacterial infection during the season when ticks are biting.

Serum procalcitonin (>2 ng/mL) and C-reactive protein (>40 mg/L) are significantly higher in patients with bacterial meningitis than in those with viral meningitis and can help in diagnosis when the results of spinal fluid analysis does not clearly differentiate one disease from the other.

Empiric therapy of bacterial meningitis is based on predisposing and associated conditions (Table 64.2). If *S pneumoniae* is a possible meningeal pathogen, empiric therapy is based on the possibility that the organism is penicillin- and cephalosporin-resistant and includes a third- or fourth-generation cephalosporin plus vancomycin. Metronidazole is added to the empiric regimen to cover anaerobic bacteria in patients with the predisposing conditions of otitis, mastoiditis, and sinusitis. Ampicillin should be added to the empiric regimen in individuals at risk for meningitis due to *L monocytogenes*. Gentamicin should be added for patients with possible *L monocytogenes* meningitis who are stuporous, obtunded, or comatose. Dexamethasone is administered either 15 to 20 minutes before the first dose of an antimicrobial agent or with the first dose of an antimicrobial agent.

Acyclovir is added to the empiric regimen for the treatment of herpes simplex virus encephalitis and doxycycline is added to the empiric regimen during the season when ticks are biting.

Once adjunctive and antimicrobial therapy have been initiated, a computed tomography (CT) scan can be obtained followed by spinal fluid analysis. The need or lack thereof for CT prior to lumbar puncture has always been controversial. In 2004, *Practice Guidelines for the Management of Bacterial Meningitis* were published by the Infectious Diseases Society of America. The practice guidelines were written by internists, a neurologist, and a pediatrician. The guidelines recommend CT prior to lumbar puncture in adult patients who meet any of the following criteria: (1) immunocompromised state due to human immunodeficiency virus infection, immunosuppressive therapy, and/or bone marrow or solid organ transplantation; (2) history of central nervous system disease (mass lesion, stroke, or focal infection); (3) new-onset seizure (within 1 wk of presentation); (4) papilledema; (5) abnormal level of consciousness; and (6) focal neurologic deficit (Level 2). The authors of the guidelines also state that some authorities would delay or not perform lumbar puncture in patients with seizures because seizures may be associated with transient increases in intracranial pressure. The 2008 European Federation of Neurological Societies guideline on the management of acute bacterial meningitis in older children and adults not only recommend that patients have brain imaging before lumbar puncture but also state that the initiation of antibiotic therapy should not be delayed beyond 3 hours after first contact with patient. The decision to perform lumbar puncture without CT if the patient has none of the six criteria listed above is certainly reasonable. As an opening pressure should be obtained in all patients with suspected bacterial meningitis, there is a degree of comfort in knowing the CT did not show a mass lesion or impending herniation when the CSF rises to the top of the manometer.

The CSF abnormalities characteristic of bacterial meningitis include the following: (1) an opening pressure greater than 180 mm H_2O, (2) a polymorphonuclear pleocytosis, (3) a low

TABLE 64.2 Empiric Antimicrobial Therapy Based on the Predisposing Condition and Meningeal Pathogen

Predisposing Condition	Bacterial Pathogen	Antibiotic
Neonates	Group B streptococcus, *Escherichia coli*, *Listeria monocytogenes*	Cefotaxime plus ampicillin
Children and adults—community acquired	*Streptococcus pneumoniae* and *Neisseria meningitidis*	Third- or fourth-generation cephalosporin plus vancomycin
Otitis, mastoiditis, sinusitis	Streptococci species, gram-negative anaerobes (*Bacteroides* species, *Fusobacterium* species), *Staphylococcus aureus*, *Haemophilus* species, Enterobacteriaceae	Third- or fourth-generation cephalosporin plus vancomycin plus metronidazole
Adults older than the age of 55 and those with chronic illness	*S pneumoniae*, gram-negative bacilli, *N meningitidis*, *L monocytogenes*, *Haemophilus influenzae*	Third- or fourth-generation cephalosporin plus vancomycin plus ampicillin
Endocarditis	Viridans streptococci, *S aureus*, *Streptococcus bovis*, HACEK group,[a] Enterococci	Third- or fourth-generation cephalosporin plus vancomycin
Immunosuppressed	*S pneumoniae*, *L monocytogenes*, *H influenzae*	Third- or fourth-generation cephalosporin or meropenem plus vancomycin plus ampicillin
Postneurosurgical	Staphylococci, gram-negative bacilli	Vancomycin plus meropenem or vancomycin plus ceftazidime
Intraventricular device	Staphylococci, gram-negative bacilli, anaerobes	Vancomycin plus meropenem or vancomycin plus ceftazidime plus metronidazole

[a]The HACEK group is *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

glucose concentration (<40 mg/dL), and (4) an elevated protein concentration. The CSF should be examined within 90 minutes after it is obtained because white blood cells begin to degrade fairly quickly and may yield a false-negative result. In patients with an elevated serum glucose concentration, a CSF-to-serum glucose ratio should be obtained. A normal CSF-to-serum glucose ratio is 0.6. A CSF-to-serum glucose ratio of less than 0.31 is seen in approximately 70% of patients with bacterial meningitis. Gram stain is positive in identifying the organism in 60% to 90% of cases of bacterial meningitis.

The CSF lactate concentration is, in general, nonspecific and the measurement of the CSF lactate concentration is not recommended for patients with suspected community-acquired bacterial meningitis. The CSF lactate concentration, however, does appear to be valuable for the diagnosis of bacterial meningitis in postoperative neurosurgical patients. In the postoperative neurosurgical patient, empiric antimicrobial therapy should be initiated if the CSF lactate concentration is greater than or equal to 4.0 mmol/L.

In clinical practice, it is important to determine early on if this is bacterial meningitis or viral meningitis in the patient presenting with fever, headache, and stiff neck. There are four tests that are most helpful in doing this: (1) the C-reactive protein, (2) the serum procalcitonin, (3) the CSF Gram stain, and (4) the CSF reverse transcriptase polymerase reaction for enteroviruses. A normal C-reactive protein has a high negative predictive value in the diagnosis of bacterial meningitis. An elevated serum procalcitonin concentration occurs in severe bacterial infections. The serum procalcitonin is an additional helpful test in differentiating bacterial meningitis from viral meningitis when the CSF Gram stain is negative. The results of a CSF Gram stain are usually available in 4 hours. The results of the CSF reverse transcriptase polymerase reaction for enteroviruses is also usually available within a short period of time.

Differential Diagnosis

As discussed, the clinical presentation of bacterial meningitis includes *two or more* of the following four symptoms and signs: (1) fever (≥38.5°C), (2) headache, (3) nuchal rigidity, and (4) an altered level of consciousness. Viral meningitis is the leading disease in the differential diagnosis of the classic triad of fever, headache, and nuchal rigidity. Spinal fluid analysis demonstrates a normal opening pressure, a lymphocytic pleocytosis, and a normal glucose concentration. Infection with *Borrelia burgdorferi* may manifest as headache and cranial nerve palsies. Spinal fluid analysis will demonstrate a lymphocytic pleocytosis with a normal glucose concentration. When impaired consciousness, focal neurologic deficits or new-onset seizures are added to the classic triad; the differential diagnosis includes viral encephalitis, intracranial venous thrombosis, tickborne bacterial infections, and infectious intracranial mass lesions. Viral encephalitis and tickborne bacterial infections often present with fever and altered level of consciousness. The opening pressure is typically elevated in viral encephalitis and tickborne bacterial infections, there is a lymphocytic pleocytosis and a normal glucose concentration. Tuberculous meningitis may also present with the apoplectic onset of fever and headache. Spinal fluid analysis demonstrates a lymphocytic pleocytosis and a decreased glucose concentration. Subarachnoid hemorrhage presents with headache and nuchal rigidity.

The differential diagnosis in human immunodeficiency virus–infected patients who present with meningeal signs, includes meningitis caused by *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, and *Treponema pallidum*.

The greatest mimic for bacterial meningitis is medication-induced "aseptic" meningitis, which may have a similar clinical presentation and spinal fluid formula as bacterial meningitis. The clinical presentation includes fever, headache, stiff neck, lethargy, confusion, seizures, and coma. Spinal fluid analysis may demonstrate an increased opening pressure, a pleocytosis of polymorphonuclear leukocytes, and a decreased glucose concentration. There may be diffuse enhancement of the meninges post the administration of contrast on CT or magnetic resonance imaging. The CSF Gram stain and culture are negative, and the symptoms resolve promptly when the offending medication is discontinued.

Cerebrospinal Fluid Analysis for the Differential Diagnosis

The CSF Gram stain and bacterial culture can identify the meningeal pathogen in approximately 80% of patients. The CSF PCR assays detect bacterial nucleic acid in CSF. A 16S rRNA conserved sequence broad-based bacterial PCR can detect small numbers of viable and nonviable organisms in the CSF, but this assay has been replaced by newer nucleic acid assays. A commonly used PCR panel is the FilmArray Meningitis/Encephalitis panel that tests six bacterial meningeal pathogens, including *S pneumoniae*, *N meningitidis*, *H influenzae*, *E coli*, group B streptococcus, and *L monocytogenes*. Specific advantages of this PCR panel are its rapid turnaround time. The sensitivity and specificity of the FilmArray Meningitis/Encephalitis panel for bacterial pathogens is not known at this time. A CSF analysis should include a nucleic acid amplification test for *Mycobacterium tuberculosis* and acid fast smear and *M tuberculosis* culture.

Metagenomic next-generation sequencing (mNGS) is a newer nucleic acid assay to identify the meningeal pathogen LEVEL 1.[1] A limitation to mNGS is that the results take time. An mNGS is particularly helpful in those instances when the pathogen is difficult to detect. The PCR assays have eliminated the need for the latex particle agglutination test, which had high specificities but variable sensitivities. A false-positive PCR is a possibility with both the meningitis/encephalitis panel and mNGS. The results of a PCR assay can be confirmed by a conventional test, such as culture, CSF immunoglobulin M, and/or acute and convalescent serology. Table 64.3 lists the CSF diagnostic studies for bacterial meningitis. In clinical practice, when bacterial meningitis is a possibility, most physicians treat with empiric therapy until CSF analysis and/or the clinical course suggests an alternative diagnosis.

TREATMENT

Once the causative organism has been identified by culture, and antimicrobial sensitivities of the organism are known, empiric therapy is modified accordingly (Table 64.4).

Both the Infectious Diseases Society of America Practice Guidelines for the Management of Bacterial Meningitis and the European Federation of Neurological Societies Guideline on the Management of Community-Acquired Bacterial Meningitis recommend the use of dexamethasone in adults with suspected or proven pneumococcal meningitis LEVEL 1.[2] The Infectious Diseases

TABLE 64.4 Recommended Doses for the Antibiotics for Bacterial Meningitis

Antibiotic Agent	Total Daily Dosage (Dosing Interval in Hours)
Ampicillin	Infants and children: 300 mg/kg/d (q6h) Adults: 12 g/d (q4-6h)
Cefepime	Infants and children: 150 mg/kg/d (q8h) Adults: 6 g/d (q8h)
Cefotaxime	Infants and children: 225-300 mg/kg/d (q6-8h) Adults: 8-12 g/d (q4-6h)
Ceftazidime	Infants and children: 150-200 mg/kg/d (q8h) Adults: 8 g/d (q8h)
Ceftriaxone	Infants and children: 80-100 mg/kg/d (q12h) Adults: 4 g/d (q12h)
Gentamicin	Infants and children: 7.5 mg/kg/d (q8h) Adults: 5 mg/kg/d (q8h)
Meropenem	Infants and children: 120 mg/kg/d (q8h) Adults: 6 g/d (q8h)
Metronidazole	Infants and children: 30 mg/kg/d (q6h) Adults: 2,000 mg/d (q6h)
Nafcillin	Infants and children: 200 mg/kg/d (q6h) Adults: 9-12 g/d (q4h)
Penicillin G	Infants and children: 0.3 mU/kg/d (q4-6h) Adults: 24 million U/d (q4-6h)
Rifampin	Infants and children: 10-20 mg/kg/d (q12-24h) Adults: 600-1,200 mg/d (q12h)
Vancomycin[a]	Infants and children: 60 mg/kg/d (q6h) Adults: 45-60 mg/kg/d (q5-12h)
Chemoprophylaxis Neisseria meningitidis	Rifampin 600 mg twice daily for 2 d or ceftriaxone 250 mg intramuscular

[a]Vancomycin can safely be given by intraventricular administration. The adult dose is 20 mg/d. The pediatric dose is 10 mg/d.

Society of America practice guidelines also acknowledged that "some authorities would initiate dexamethasone in all adults with suspected bacterial meningitis because the etiology of meningitis is not always ascertained at initial evaluation." A favorable trend toward reduced rates of death and hearing loss and no evidence that dexamethasone was harmful in patients with meningococcal meningitis has been subsequently demonstrated since the publication of the 2004 guidelines LEVEL 2.[3] Dexamethasone decreases the production of the inflammatory cytokines and stabilizes the blood-brain barrier (Fig. 64.2). As such, dexamethasone is efficacious in attenuating the neurologic complications that evolve as a result of the production of inflammatory cytokines and an increased blood-brain barrier permeability. The recommended dose is 0.6 mg/kg daily in four divided doses (0.15 mg/kg/dose) given intravenously for the first 4 days of antibiotic therapy for infants 2 months of age and older and children. The dose of dexamethasone for adults is 10 mg every 6 hours for the first 4 days of antibiotic therapy. The first dose of dexamethasone should be administered 15 to 20 minutes before or at least with the first dose of antibiotics.

The American Academy of Pediatrics recommends the consideration of dexamethasone for bacterial meningitis in infants and children 6 weeks of age or older. The recommended dose is the same as for adults, and the first dose should be administered 15 to 20 minutes before or at least with the first dose of antibiotics. Results of clinical trials of dexamethasone therapy in children have demonstrated its efficacy in decreasing meningeal inflammation and neurologic sequelae and in reducing the incidence of sensorineural hearing loss in bacterial meningitis from any cause.

COMPLICATIONS

Patients with bacterial meningitis should be admitted to the neurocritical care unit. Eradicating the meningeal pathogen is the easy step. The neurologic complications of cerebral edema, focal and diffuse cortical hypoperfusion, disturbed cerebral autoregulation, septic sinus thrombosis, intracerebral hemorrhage, hydrocephalus, and seizures are responsible for both the mortality and the sequelae of bacterial meningitis. The management of the neurologic complications is thus critical to the patient's outcome. Increased intracranial pressure is treated with elevation of the head of the bed, osmotic diuretics (eg, mannitol), and hyperventilation (see Chapter 111). Sedation with anesthetic agents to decrease cerebral metabolism should also be considered. An intracranial pressure monitoring device should be used in stuporous or comatose patients to guide therapy of intracranial pressure. Cerebral perfusion pressure should be maintained between 50 and 70 mm Hg. Cerebral ischemia and intracerebral hemorrhage have a high risk of morbidity, and therapeutic agents that treat these complications would be of tremendous benefit to patients.

65 Brain, Spinal, and Epidural Abscess and Other Parameningeal Infections

Tracey A. Cho

KEY POINTS

1. Brain abscess may result from direct extension of infection in the frontal or ethmoid sinuses (frontal lobe), middle ear (cerebellum or temporal lobe), or odontogenic infection (frontal lobe).
2. Multiple abscesses in the distribution of the middle cerebral artery are most likely due to hematogenous spread from an extracranial source.
3. Restricted diffusion on magnetic resonance imaging (MRI) may be useful in distinguishing bacterial brain abscess from tumor.
4. The standard treatment of bacterial brain abscess is stereotactic aspiration to identify the pathogen and reduce the abscess burden.
5. An MRI of bacterial brain abscess may show some persistent enhancement even after adequate treatment, and this MRI finding should not be used in isolation to guide any further treatment.
6. Subdural empyema progresses more rapidly than brain abscess, typically with fever, focal headache, and rapidly progressive neurologic deficits and/or seizures.
7. Spinal epidural abscess is a surgical emergency because medical management alone is often insufficient, and the degree of neurologic deficit prior to treatment is the most important modifiable factor in outcomes.

BRAIN ABSCESS

A brain abscess is a focal purulent infection within the brain parenchyma caused by bacteria, mycobacteria, fungi, protozoa, or helminths. A brain abscess starts as a localized area of cerebritis; abscesses vary in size from a microscopic collection of inflammatory cells to an area of purulent necrosis presenting as a mass lesion.

Advances in the diagnosis and treatment of brain abscesses have been achieved with the use of computed tomography (CT), magnetic resonance imaging (MRI), especially diffusion-weighted imaging (DWI), stereotactic brain biopsy and aspiration, and newer broad-spectrum antibiotics.

Epidemiology

The incidence of brain abscess ranges from 0.4 to 0.9 cases per 100,000 person-years. A brain abscess is 2 to 3 times more common in males than in females, with the highest incidence occurring in fourth decade of life. Up to 86% of patients have a predisposing condition, with an increasing number of patients developing abscess in the setting of iatrogenic immunosuppression. Over the past several decades, advances in management of brain abscesses have resulted in a significant decline in mortality from 30% to 50% before 1980, to 4% to 20% more recently. Up to 25% of all cases occur in children younger than 15 years old, with a cluster in the 4- to 7-year-old age group, usually the result of cyanotic congenital heart disease or an otic infection.

Source of Infection in Brain Abscess

Classifying brain abscess based on the likely source of infection is useful for determining the evaluation for predisposing factors and identifying appropriate empiric antimicrobial therapy. A brain abscess may develop from any of the following predisposing or associated conditions: (1) direct extension of cranial infection, ethmoid or frontal sinusitis, subacute or chronic otitis media, mastoiditis, or dental infection; (2) direct inoculation via wounds, fracture of the skull, or neurosurgical procedures; and (3) hematogenous dissemination of infection from elsewhere in the body (eg, lung abscess, bacterial endocarditis, intra-abdominal infections, dental infections, congenital heart disease). Twenty percent to 30% of brain abscesses have no obvious source and are so-called cryptogenic brain abscesses; many of these are presumed to be odontogenic.

Infection in the middle ear or mastoid may spread to the cerebellum or temporal lobe through involvement of bone and meninges or by seeding of bacteria through valveless emissary and sinus veins that drain these regions. Infection may originate from tonsils or abscessed teeth, or frontal, ethmoid, or rarely the maxillary sinuses, with sinus infections often spreading to frontal lobes through erosion of the skull. Odontogenic brain abscess occurs in the setting of tooth extraction or other dental manipulation, most commonly in the frontal lobe. Brain abscess rarely complicates bacterial meningitis, with the exception of neonatal meningitis due to gram-negative enteric organisms including *Proteus* and *Enterobacter* species; for unclear reasons, these species tend to cause abscesses in neonates.

For hematogenous spread, cerebral lesions are found in distal territories of the middle cerebral artery and frequently are multiple, often seen at the junction of gray-white matter. Potential sources for hematogenous spread of infection include upper respiratory tract (lung abscess or empyema), bacterial endocarditis, skin infections, intra-abdominal, or pelvic infections. Congenital cardiac defects and pulmonary arteriovenous malformations (eg, hereditary hemorrhagic telangiectasia) predispose to brain abscess. In these two disorders, infected emboli bypass pulmonary filtration system and gain access to the cerebral arterial system. Similarly, cases of cryptogenic brain abscess caused by vegetations on patent foramen ovale or right-to-left shunting

TABLE 65.1 Brain Abscess

Source	Pathogen
Oral cavity, hematogenous spread (intra-abdominal/pelvic infections), otitis, mastoiditis, paranasal sinusitis	Streptococci species (aerobic and anaerobic), *Staphylococcus aureus*, *Bacteroides* species, *Pseudomonas* species, *Haemophilus* species, *Enterobacteriaceae*, *Prevotella melaninogenica*, *Fusobacterium* species
Trauma/neurosurgical procedure	*S aureus* or *Staphylococcus epidermidis*, *Streptococcus* species, *Enterobacteriaceae*, *Pseudomonas* species, *Clostridium* species
Pyogenic lung infections	Streptococci, staphylococci, *Bacteroides* species, *Fusobacterium* species, *Enterobacteriaceae*
Cardiac origin (eg, cyanotic heart disease, right-to-left shunts, bacterial endocarditis)	*Streptococcus* species, *Serratia marcescens*, methicillin-resistant *S aureus* (MRSA)
Immunocompromised	*Pseudomonas*, *Toxoplasma*, *Listeria*, *Nocardia*, *Aspergillus*, *Cryptococcus*, *Coccidioides*, *Mycobacterium tuberculosis*, *Enterobacteriaceae*, other fungal pathogens
Parasitic infections	*Cysticercosis*, *Entamoeba histolytica*, *Schistosoma*, *Paragonimus*

via patent foramen ovale have been reported. In infants and children, congenital heart disease is a common predisposing factor for brain abscess. The predisposing conditions of hereditary hemorrhagic telangiectasia or Rendu-Osler-Weber disease can be the source of a brain abscess via paradoxical septic emboli from lung.

A brain abscess can occur following penetrating head injury or neurosurgical procedures, although occurrence of abscesses after penetrating brain injury is low.

Causative Organisms of Brain Abscess

The infecting organism varies with site of entry, age of the patient, and immune status. Although variations exist across continents and age, the most common causes overall are streptococci (anaerobic, aerobic, or microaerophilic species), *Staphylococcus aureus*, gram-negative enteric organisms (*Proteus* species, *Klebsiella pneumoniae*, *Escherichia coli*, *Enterobacteriaceae*), *Pseudomonas* species, and anaerobes such as *Bacteroides* species (Table 65.1). In infants, gram-negative organisms are the most frequent isolates. In adult patients with direct spread of infection from an otogenic source, the most common organisms are streptococci, *Bacteroides* species, *Pseudomonas* species, *Enterobacteriaceae*, and *Haemophilus*. Other causative organisms from oral or hematogenous spread include streptococci, *S aureus*, *Bacteroides* species, and *Fusobacterium* species. After penetrating head injury or neurosurgical procedure, abscess formation is usually due to *S aureus* (methicillin-resistant *S aureus* or MRSA), *Staphylococcus epidermidis*, streptococci, *Enterobacteriaceae*, *Pseudomonas* species, or *Clostridium* species. Brain abscesses as a complication of bacterial endocarditis are due to streptococci, MRSA, and *Serratia marcescens*.

In the immunocompromised host, *Toxoplasma*, *Listeria*, *Nocardia*, *Aspergillus*, *Cryptococcus*, *Coccidioidomycosis*, *Mycobacterium tuberculosis*, *Enterobacteriaceae*, and other fungal pathogens are causative organisms of brain abscess. In resource-rich countries, *Toxoplasma gondii* is the most common cause of rim-enhancing mass lesions of the brain in advanced human immunodeficiency virus (HIV), whereas tuberculosis is an important cause in both low and high resource settings. In solid organ transplant patients, up to 90% of brain abscesses are due to fungal infection. Brain abscess may also be due to a parasitic infection such as *Entamoeba histolytica*, cysticercosis, *Schistosoma*, or toxocariasis; the imaging pattern (cystic) and demographic exposure usually distinguish these parasitic infections from more typical pyogenic abscess.

Cultures may be sterile in patients who have received antimicrobial therapy before biopsy, but any material obtained should be sent to the laboratory. A positive Gram stain guides therapy even when the culture is negative. Depending on the study, microbiologic diagnosis is obtained in 68% to 83% of cases; brain abscess is polymicrobial in 23% of cases.

Pathobiology

The pathologic changes in brain abscesses are similar regardless of the origin: direct extension to the brain from a contiguous site of infection, retrograde thrombosis of veins, or hematogenous dissemination (Fig. 65.1).

Based on animal models and human imaging studies, abscess formation occurs through a continuum of changes. Focal infection (cerebritis) starts as an area of inflammation, which correlates with patchy T2 hyperintensity on MRI (hypodensity on CT), followed by central necrosis with surrounding edema, leading to rim-enhancement along the edge of inflammation and

FIGURE 65.1 Brain abscess. Abscess in frontal lobe secondary to pulmonary infection. (Courtesy of Dr. Abner Wolf.)

surrounding T2 hyperintensity. When host defenses control the spread of the infection, macroglia and fibroblasts proliferate in an attempt to surround the infected and necrotic tissue, and granulation tissue and fibrous encapsulation develop, often thicker on the cortical versus ventricular side owing to increased vascular supply. If the capsule ruptures, purulent material is released into the ventricular system, a process associated with a high mortality rate. Edema surrounding a brain abscess is common. The process from brain inoculation to mature capsule formation takes 2 weeks or longer depending on the organism.

Two signal-mediated central nervous system immune responses to invading pathogens that may be important in the developing abscess include the Toll-like and Nod-like receptors systems. Activation of Toll-like receptor by invading pathogens leads to a complex array of immune-mediated response including control of infection burden, immune infiltrates, and inflammatory mediators. Likewise, Nod-like receptor activates a number of immune-specific interleukins responsible for bacterial recognition and subsequent cytokine release that acts to restrict bacterial spread during abscess formation.

Clinical Manifestations

The symptoms of a brain abscess are typical of an expanding mass lesion in the brain with elevated intracranial pressure (ICP) and include headache with or without fever as the initial symptoms, followed by nausea, vomiting, lethargy, and focal neurologic deficits. Headache occurs in about 70% of patients. Sudden worsening of preexisting headache, new-onset nuchal rigidity, and seizures may herald rupture of brain abscess into the ventricular space. The average duration of symptoms prior to presentation is 8.3 days. The abrupt onset of a severe headache is less common with abscess and is more often associated with acute bacterial meningitis or subarachnoid hemorrhage. Fever is present in 53% of patients and focal neurologic deficits in 48%, but the classic combination of headache, fever, and focal deficits occurs in only 20%.

Focal neurologic deficits vary with abscess location. Hemiparesis, apathy, and confusion may be seen with lesions of the frontal lobe, hemianopia, and aphasia, particularly anomia, with abscesses in the temporal or parietooccipital lobes and ataxia, intention tremor, nystagmus, with cerebellar abscess (**Fig. 65.2**). Seizures (focal or generalized), nuchal rigidity, and papilledema are also common with abscess (around 30% of cases for each symptom). The presence of papilledema and/or third or sixth cranial nerve palsies are typically due to increased ICP.

Abscesses in the brainstem are rare. The classic findings of brainstem syndromes are often lacking because abscess tends to expand longitudinally along fiber tracts rather than transversely. Subdural or, rarely, epidural infections in the frontal regions

FIGURE 65.2 Cerebellar abscess with mastoiditis. **A:** Sagittal magnetic resonance imaging T1-weighted image after gadolinium administration demonstrates ring enhancement *(white arrow)* of cerebellar abscess. **B:** Complication of mastoiditis with bilateral transverse sinus thrombosis as seen on magnetic resonance venogram *(arrows)*. **C:** Computed tomography bone windows demonstrating sclerotic change of the right mastoid sinus *(left arrow)*, consistent with chronic mastoiditis. (Courtesy of Dr. William Wagle.)

may present with the same signs and symptoms as those of an abscess in the frontal lobe. Fever and focal seizures favor the diagnosis of subdural rather than intraparenchymal abscess, although these findings are not specific.

Transverse sinus thrombosis often follows middle ear or mastoid infection (see Fig. 65.2) and may be accompanied by seizures and signs of increased ICP, making the clinical differentiation between this condition and abscess of the temporal lobe or hemispheres difficult. With transverse sinus thrombosis, papilledema may result from blockage of venous drainage from the brain. Focal neurologic signs favor the diagnosis of abscess.

Diagnosis

Brain abscess should be suspected when seizures, focal neurologic signs, or increased ICP develops in a patient with known acute or chronic infection in the middle ear, mastoid, nasal sinuses, heart, or lungs and in those with congenital heart disease. Neuroimaging by CT or MRI is essential to making the diagnosis.

Although CT scan can be useful for identifying hemorrhage or calcification, MRI is the neuroimaging study of choice both for diagnosis and treatment of brain abscess and should include basic T2 and T1 pre- and postcontrast sequences, plus fluid-attenuated inversion recovery (FLAIR), DWI, apparent diffusion coefficient (ADC), and susceptibility weighted imaging. Abscesses are frequently found in the gray-white junction in watershed regions between vascular territories. Imaging features of abscess include a T2/FLAIR hyperintense, T1 hypointense core; T2/FLAIR hypointense periphery; and rim-enhancement on postcontrast T1 sequences (Fig. 65.3). Due to the dense purulent core, water movement is usually impaired leading to hyperintensity on DWI and hypointensity on ADC. With a mature encapsulated abscess, both contrast CT and MRI with gadolinium reveal the ring-enhancing mass with surrounding vasogenic edema. As noted earlier, the cortical edge of the abscess often demonstrates thickening compared to the medial edge, which can help differentiate abscesses from tumors or demyelination.

An MRI permits accurate localization of cerebritis or abscess and serial assessment of the size of the lesion, its demarcation, the extent of surrounding edema, and total mass effect and allows for staging of the abscess. Although magnetic resonance spectroscopy has been studied as a way to help differentiate brain abscesses based on metabolic patterns of lactate, amino acids, or acetate from other similar-appearing lesions (eg, tumor), its value beyond that of DWI in this setting is limited, and it is not routinely used in practice.

The differential diagnosis, based on the appearance of lesions seen on CT or MRI, includes glioblastoma, metastatic tumor, infarct, arteriovenous malformation, resolving hematoma, and granuloma. Features supporting the diagnosis of brain abscess include gas within the center of a ring-enhancing lesion, a thinner enhancing rim (<5 mm) than with brain tumors, more

FIGURE 65.3 Brain abscesses. **A-I:** Magnetic resonance imaging (MRI) T1-weighted images **(A,B)** show right frontal lobe abscess with adjacent, smaller anterior-located abscess with typical ring enhancement after gadolinium administration **(C,D)**. FIGURE 65.3 *(continued)* MRI diffusion-weighted images show typical bright-appearing lesions of abscess **(E,F)**. The brain abscesses with evidence of edema and mass effect are seen on MRI fluid-attenuated inversion recovery and T2-weighted images **(G,H)**. MRI sagittal T1-weighted images postgadolinium show enhancing frontal sinus infection with direct extension to brain parenchyma and ventricles **(I)**. Bright signal seen in ventricles on T1-weighted image after gadolinium is indicative of ventriculitis. (Courtesy of Dr. James Thomas.)

regular borders with ringlike enhancement, and ependymal enhancement associated with ventriculitis or ventricular rupture (see Fig. 65.3). An MRI with DWI and ADC may aid in differentiating tumor from abscess. With brain abscess, MRI DWI signal is hyperintense with associated low ADC values, compared to brain tumor with isointense or hypointense DWI appearance but high ADC. In one study of 147 cystic brain lesions, this pattern had a sensitivity of 96% and a specificity of 96% for differentiating abscess from noninfectious causes. Unlike pyogenic brain abscesses, the signal of *Toxoplasma* abscesses may not be hyperintense on DWI MRI. In the right setting, empiric treatment for *Toxoplasma* can be initiated with evaluation for responsiveness to treatment using follow-up MRI imaging several weeks later.

Either CT or MRI may distinguish abscess from mycotic aneurysms or herpes encephalitis, each of which may cause similar symptoms and signs. Mycotic aneurysm, usually in the distribution of the middle cerebral arteries, may be accompanied by meningitis in bacterial endocarditis. A CT or MRI may exclude abscess, but CT angiography is often necessary to identify the aneurysm before rupture. Herpes simplex encephalitis presents with headache, fever, and an acute temporal lobe or frontal lobe syndrome. On CT or MRI, the temporal lobe is swollen, with irregular lucency and patchy contrast enhancement.

Both erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be elevated in patients with brain abscess, 72% and 60%, respectively, in a large meta-analysis but with many patients demonstrating normal values. Blood cultures are positive in patients with hematogenous dissemination as the source of infection, up to 28% of cases overall. An HIV status should be confirmed in all patients with suspected brain abscess; if HIV-positive, serum toxoplasma immunoglobulin G should be tested.

Lumbar puncture adds little to the diagnosis outside the setting of meningitis and is contraindicated in patients suspected of having a brain abscess prior to neuroimaging because of the risk of transtentorial or uncal herniation.

Extension of the abscess to the meninges or ventricles is accompanied by findings associated with acute meningitis or ventriculitis. Rupture of an abscess into the ventricles is signaled by a sudden rise in ICP and the presence of free pus, with marked increases in cerebrospinal fluid cell count to levels of 20,000/mm^3 to 50,000/mm^3. A decrease in glucose content below 40 mg/dL indicates that the meninges have been invaded by bacteria. Only rarely are cerebrospinal fluid cultures positive.

Management

The introduction of CT revolutionized the management of brain abscess. Now, with MRI, it is possible to diagnose and localize cerebritis or abscess, dictate choice of treatment, and monitor patient response. Current recommended treatment for most brain abscesses is stereotactic aspiration to obtain specimens for culture and special studies and guide treatment with appropriate antimicrobial therapy.

Surgical treatment in the past included open evacuation and excision or freehand needle aspiration through burr hole. Currently, most surgeons prefer CT- or MRI-guided stereotactic aspiration and drainage. This method is the treatment of choice for most abscesses, particularly those that are deep-seated, multiple, or located in eloquent areas of the brain. Empiric antimicrobial therapy is based on Gram stain results from the specimen obtained by stereotactic aspiration and on the presumptive source of the abscess. Open craniotomy with excision is now performed

TABLE 65.2 Specific Intravenous Antimicrobials for Treatment of Brain Abscess

Vancomycin[a]	45-60 mg/kg/d, every 6-12 h
Meropenem	2 g every 8 h (used as first-line or second-line therapy)
Cefotaxime	2 g every 4-8 h (maximum 12 g/d)
Ceftriaxone	2 g every 12 h (maximum 4 g/d)
Ceftazidime	1-2 g every 4-8 h (maximum 6 g/d)
Cefepime	2 g every 8 h (maximum 6 g/d)
Metronidazole	500 mg every 6 h (1,500-2,000 mg/d)
Voriconazole	Loading dose of 6 mg/kg every 12 h × 2, followed by 4 mg/kg every 12 h

[a]Doses adjusted based on serum peak and trough levels; adjusted based on creatinine clearance.

infrequently and is reserved for patients with multiloculated abscesses, those with antimicrobial-resistant pathogens, abscesses due to *Nocardia*, abscesses containing gas resistant to antibiotics, and posttraumatic abscesses containing foreign bodies or contaminated bone fragments.

Choosing the appropriate antimicrobial therapy depends on the ability of the drug to penetrate the abscess cavity and its activity against the suspected pathogen. Penicillin and chloramphenicol were standard therapy for brain abscesses at one time, but they are rarely used today. These have been replaced by vancomycin, third- and fourth-generation cephalosporins (eg, cefotaxime, ceftriaxone, ceftazidime, and cefepime), metronidazole, and meropenem (Table 65.2). Combination therapy with third- or fourth-generation cephalosporins and vancomycin appears to be highly effective for empiric treatment of most brain abscesses. Metronidazole is added when otitis, mastoiditis, or paranasal sinusitis is the suspected source of infection. Additional antibiotic coverage may be needed for some organisms (eg, *Actinomyces* species) when the abscess is secondary to dental procedures or dental abscess. Special consideration of antimicrobial coverage must be given for *Enterobacteriaceae* or *Pseudomonas aeruginosa*, particularly when an otogenic source of brain abscess is suspected. Vancomycin plus a third-generation cephalosporin may be given initially in cases of brain abscess from neurosurgical procedures while awaiting final culture results. Vancomycin is also used in cases of MRSA abscesses. The rare tuberculosis abscesses can be treated with combination of isoniazid, rifampin, ethambutol, and pyrazinamide for 2 to 4 months, and thereafter, isoniazid and rifampin are given for at least 1 year. Aspergillosis abscesses are most effectively treated with voriconazole. Amphotericin B may be considered if voriconazole cannot be given. The duration of antibiotics for most abscesses is 4 to 8 weeks depending on the context, although randomized clinical trials are lacking. For cerebritis without capsule formation, and for simple abscesses surgically drained, a shorter duration (4-6 wk) is sufficient. When there are complicating factors such as multilobulated abscess, immunocompromised, or lesions inaccessible to drainage, then longer courses (6-8 wk or longer) are recommended.

Clinical improvement and CT or MRI are used to monitor the effectiveness of antibiotic treatment. The appropriate frequency of imaging surveillance is variable. For patients who are clinically improving, a 6-week interval is reasonable; patients with ongoing fever or incomplete clinical response require more frequent imaging. Follow-up CT and MRI may show a small area of residual enhancement even after adequate antimicrobial therapy

and should not be used in isolation to guide ongoing antimicrobials if clinical and other imaging parameters are improving. Occasionally, a previously ring-enhancing lesion on CT disappears with medical management, suggesting that these reversible lesions are forms of suppurative cerebritis.

Seizures may occur in up to 50% of patients with brain abscess early in the course, but the incidence is variable and unpredictable; one large retrospective study found seizures in only 16% of patients with brain abscess. Extrapolating from studies in brain tumors, anticonvulsants should not be used routinely for primary prophylaxis.

The use of corticosteroids for these patients is controversial. In patients with life-threatening cerebral edema, midline shift, or impending herniation, a short course of high-dose corticosteroids (dexamethasone 10 mg intravenously once, then 4 mg intravenously every 6 h) may be appropriate. Corticosteroids should be discontinued once the patient is improved. Prolonged use of corticosteroids is not recommended because the steroids may interfere with granulation tissue formation and reduce the concentration of antibiotics within the infected tissue. Patients with severe brain edema may require intubation with intensive care management to control elevated ICP. Hemicraniectomy may be considered in cases of increased ICP refractory to medical therapy.

Outcome

The outcome of untreated brain abscess is, with rare exceptions, death. Mortality in pre-CT series varied from 35% to 55%. In the era of advanced neuroimaging with CT and MRI, the mortality rate of brain abscesses is as low as 10%. Overall morbidity and mortality of brain abscess is related to delayed diagnosis, presence of single or multiple abscesses, intraventricular rupture, presence of coma or rapidly declining neurologic status at the time of diagnosis, or fungal infections. Patients with depressed level of consciousness on admission tend to do poorly. Intraventricular rupture of a brain abscess and posterior fossa location are associated with mortality rates exceeding 80%. In a univariate analysis of mortality, Glasgow Coma Scale score on admission of less than or equal to 9 was an independent predictor of in-hospital mortality in one study. Immunocompromised individuals have worse outcomes and higher mortality rates. The highest death rate is found when the primary infection is in the lungs.

Sequelae of brain abscess include recurrence of the abscess or the development of new abscesses if the primary focus persists. Residual neurologic sequelae with hemiparesis, seizures, or intellectual or behavioral impairment are common; however, over five decades up to 2012, the number of patients with full recovery increased from about 30% to 70% of patients.

SUBDURAL EMPYEMA

A subdural empyema is a collection of loculated pus in the subdural space. The symptoms are similar to those of a brain abscess, although symptoms progress more rapidly.

Epidemiology

Unlike other suppurative infections of the cranium and parameningeal space, most patients are healthy without predisposing conditions apart from sinusitis. A subdural infection in adults usually arises from a contiguous spread of infection; paranasal sinusitis is the most common source. Otitis, head trauma, and neurosurgical procedures are other sources of infection. The most common pathogens in subdural empyema are anaerobic organisms and microaerophilic streptococci. In a minority of cases, *S aureus* and multiple organisms, including gram-negative organisms such as *E coli* and anaerobic organisms, such as *Bacteroides*, may be present. *P aeruginosa* or *S epidermidis* may be found in cases following neurosurgical procedures. In addition, *Clostridium perfringens* subdural empyemas can occur from the site of recent surgical wound or trauma.

Pathobiology

The infection spreads to the subdural space through retrograde thrombophlebitis via venous sinuses or direct extension through bone and dura. Once the infection develops, it may spread over the convexities and along the falx, although characteristic loculation is common. Associated complications include septic cortical vein thrombosis, brain or epidural abscess, and meningitis. Infratentorial empyema is a rare complication of bacterial meningitis and can present with nonlocalizing symptoms of neck stiffness and decreased level of consciousness.

Clinical Manifestations

Subdural empyema typically presents with focal headache, fever, and in 80% to 90% of patients, focal neurologic signs. The combination of fever, rapidly progressive neurologic deterioration, and focal seizures is particularly suggestive of this disorder. Symptoms of subdural empyema may begin 1 to 2 weeks after a sinus infection, but the organisms most frequently involved point to chronic sinusitis as the cause in most cases.

Diagnosis

Neuroimaging with either CT or MRI reveals a typical crescent-shaped area of hypodensity or hyperintensity, respectively, over a hemisphere, along the dura, or adjoining the falx, with enhancement of the margins around the empyema after administration of contrast. The diagnostic test of choice is MRI with gadolinium enhancement for the delineation of the presence and extent of the subdural empyema and to identify concurrent intracranial infections. As with brain abscess, DWI may help distinguish empyema from noninfectious subdural collections (**Fig. 65.4**). The CT may miss some lesions that can be detected by MRI, but given the rapid progression and the potential involvement of sinus defects, CT remains an essential part of the evaluation. Lumbar puncture is generally contraindicated for the same reason it is with brain abscess, that is, because of mass effect and potential for herniation as well as the low yield.

Management

Treatment of nearly all cases of subdural empyema is immediate surgical drainage and antibiotic therapy. Intravenous antibiotics are given depending on the organism identified, or if unknown, empiric treatment with third-generation cephalosporin plus metronidazole, with adjustments based on predisposing or associated conditions. Anticonvulsants are used if patients develop seizure. There is controversy about which type of neurosurgical technique is useful for drainage of subdural empyema. A CT

FIGURE 65.4 Subdural empyema. Magnetic resonance imaging fluid-attenuated inversion recovery **(A)** and diffusion-weighted imaging **(B)** images showing hyperintense signal in the right parietal convexity and left posterior parafalcine subdural spaces *(arrowheads)* consistent with subdural empyema (no evidence of blood products on susceptibility weighted imaging; no contrast-enhanced images obtained due to renal failure). (Courtesy of Drs. Girish Bathla and Michihiko Goto.)

accurately localizes the pus collection, and some advocate drainage through selective burr holes. Others prefer open craniotomy for more complete removal of the infection, especially when the empyema is loculated. Limited craniotomy is also used for placement of a drain into the subdural space and for local infusion of antibiotics. Use of either burr hole or craniotomy for drainage of subdural empyema is individualized. Neuroendoscopic technique for drainage of both brain abscess and subdural empyema is an alternative to surgical treatment. In cases of fulminant subdural empyema, decompressive craniectomy, irrigation of the empyema, and subdural drainage may be required. Further surgery to address sinusitis or bony defects is often performed simultaneously. The recommended duration of antibiotic therapy is 4 to 6 weeks after surgical drainage, with at least 2 weeks given intravenously.

Outcome

Antibiotics and advances in neuroimaging have dropped the mortality in subdural empyema to around 6% to 15%. Despite this improved survival, morbidity remains high with seizures, hemiparesis, or other residual neurologic deficits in about 50% of cases.

SPINAL EPIDURAL ABSCESS

Spinal epidural abscess is infection in the epidural space around the spinal cord.

Epidemiology and Pathobiology

Spinal epidural abscess may arise from hematogenous spread from a distant site; direct inoculation; or contiguous spread from skin, soft tissue, or bone infection. Typically, spinal epidural abscess is associated with diabetes, trauma, intravenous drug use, alcohol, age, or immunosuppression with the single most important risk factor being diabetes. The most important pathogen for spinal epidural abscess is *S aureus* found in over 60% of cases. Most common sources of infection are skin abscesses and bony infections involving the spine. An outbreak of fungal infection from contaminated corticosteroids used for epidural injection highlights the importance of identifying potential sources of direct inoculation. The most common location of spinal epidural abscesses is in dorsal epidural space, although one 10-year study found up to 30% may be located in the ventral epidural space. Due to the increased epidural space and fat, thoracic and lumbar regions are more commonly affected than cervical.

Clinical Manifestations

The clinical presentation of spinal epidural abscess includes back pain in about 75% and fever in about 50% of patients. These symptoms commonly are followed by focal neurologic deficits in about 30%, including radiculitis, paraparesis, sensory level, bladder or bowel dysfunction, and eventual para- or quadriplegia.

Diagnostic Testing

Both ESR and CRP are invariably elevated. Complete blood count and blood cultures should be obtained. Lumbar puncture is generally contraindicated because it can lead to introduction of infection into subarachnoid space and carries a low microbiologic yield. The MRI is more sensitive than CT with contrast in identifying spinal epidural abscess, with MRI approaching 90% sensitivity in some studies. Additional benefits of MRI include the ability to detect cord involvement (swelling or necrosis), diskitis, and osteomyelitis (Fig. 65.5).

FIGURE 65.5 Spinal epidural abscess. Sagittal and axial magnetic resonance imaging T2-weighted images showing hyperintense signal **(A,B)** and sagittal and axial T1-weighted postcontrast images showing contrast-enhancement **(C,D)** in posterior epidural space at the T5-T6 spinal levels, consistent with abscess. Note additional involvement of posterior vertebral elements, paravertebral soft tissues, and paravertebral muscles consistent with contiguous osteomyelitis and myositis. (Courtesy of Drs. Girish Bathla and Michihiko Goto.)

Management

Treatment for spinal epidural abscess includes emergent surgery (eg, decompression with laminectomy) and antibiotics. Initial antimicrobial therapy should include antibiotics for MRSA and gram-negative bacilli. A combination of a third- or fourth-generation cephalosporin and vancomycin are recommended. Once the specific organism is identified from surgical specimen and antimicrobial sensitivity, then antibiotic therapy is modified accordingly. Some reports suggest spinal epidural abscess can be successfully treated with antibiotics alone (before neurologic symptoms appear); however, surgical decompression and drainage remains the mainstay of treatment in most cases.

Outcome

The prognosis in spinal epidural abscess is dependent on the degree of injury prior to treatment. The mechanism causing the neurologic deficits may also impact recovery: Compression of the cord can be helped by prompt surgical decompressions, but deficits due to vascular ischemia, with thrombosis or thrombophlebitis involving surrounding leptomeningeal vessels, or inflammatory response of glial cells, are not improved by surgery. Rehabilitation can significantly affect outcome in spinal epidural abscess, and improvement may be seen for up to a year after treatment.

MALIGNANT OTITIS EXTERNA

Malignant (necrotizing) otitis externa is an invasive infection of the external auditory canal and skull base; it penetrates epithelium and spreads to surrounding soft tissue to cause cellulitis and abscess. If untreated, the infection may extend to the temporomandibular joint, mastoid, or more commonly to soft tissues below the temporal bone.

Epidemiology and Pathobiology

Malignant otitis externa occurs more frequently in elderly diabetic patients and immunocompromised persons (eg, patients with HIV, chemotherapy, or organ transplantation) than in immunocompetent individuals.

In most cases, *P aeruginosa* is the causative organism. Less often, cases of malignant otitis externa have been reported due to *Klebsiella*, *S aureus*, *Proteus mirabilis*, and other *Pseudomonas* species. In HIV-positive individuals or in AIDS, either *P aeruginosa* or the fungus *Aspergillus fumigatus* may be isolated. In some patients with AIDS, *Streptococcus*, *Staphylococcus*, and *Proteus* species may be isolated as mixed or sole pathogens. Interestingly, ear irrigation with water contaminated with *Pseudomonas* species is often the causative event leading to malignant otitis externa.

Clinical Manifestations

Common symptoms of malignant otitis externa are severe otalgia that worsens at night, purulent otorrhea, and painful swelling of surrounding tissues. Conductive hearing loss may result from obstruction of the external auditory canal. Trismus may indicate irritation of the masseter muscles or involvement of the temporomandibular joint. Owing to its anatomic location in the temporal bone and petrous apex, the facial nerve may be affected as the first symptom in up to 30% of patients. Facial nerve involvement is most common, followed (in order) by glossopharyngeal, vagal, and spinal accessory nerves at the jugular foramen; hypoglossal nerve as it exits the hypoglossal canal; and trigeminal and abducens nerves at the petrous apex. Olfactory, oculomotor, and trochlear nerves are spared. Rarely, dysphagia results from lesions of cranial nerves IX to XII, and the findings may be mistaken for laryngeal carcinoma. Fever and weight loss are uncommon. Mastoid tenderness is evident on examination. The diagnostic finding of granulation tissue, stemming from extension of infection to the cartilaginous portion of the ear canal, may be seen on otoscopic examination. In rare cases, meningitis, brain abscess, and dural sinus thrombophlebitis can occur and are often fatal.

Diagnosis

The diagnosis of malignant otitis externa is often initially missed but can be made by combination of clinical, laboratory, and radiologic findings. General laboratory testing is invariably normal with the exception of ESR and CRP, which are elevated. The ESR is almost always elevated at greater than 50 mm/h. Both ESR and CRP can be useful in monitoring disease activity.

A CT is most useful in showing the location and extent of disease and evaluating evidence of bony erosion but may appear normal early in the illness. Initial CT can help predict severity of disease course based on early findings of extension of infection beyond the external auditory canal. The presence of bone erosion along with soft-tissue abnormalities in the subtemporal area is almost pathognomonic for the disease. An MRI with and without gadolinium is not useful in detecting bony changes but can provide useful information regarding the extent of skull-base and intracranial soft-tissue involvement. Bone scanning with technetium 99m (scans) methylene diphosphonate can be very sensitive but not specific. Gallium 67 single-photon emission computed tomography may be more sensitive and accurate in early detection of malignant external otitis, sensitive in measuring ongoing infectious process, and beneficial in monitoring response to therapy. However, it remains less frequently used compared to serial CT scanning.

The differential diagnosis of malignant otitis externa includes squamous cell carcinoma of the temporal bone. Radiologic testing cannot differentiate tumor from necrotizing infection of malignant otitis externa and biopsy is often necessary to distinguish between these two processes. Findings of positive culture for *Pseudomonas* species along with elevated ESR and CRP confirm the diagnosis of malignant otitis externa.

Management and Outcome

Antipseudomonal agents are the agents of choice for treatment of malignant otitis externa (Table 65.3). Rare cases of fungal (eg, *Aspergillus* species) malignant external otitis do exist. In the preantibiotic era, mortality rates were greater than 50%, and surgical debridement was the treatment of choice. Later, standard treatment with intravenous antibiotics consisted of an antipseudomonal penicillin for 4 to 8 weeks, combined with an aminoglycoside for at least 2 weeks, or if tolerated, 4 to 6 weeks. Current successful treatment is based on single-drug therapy. Advantages of quinolones include low toxicity, excellent penetration into bone, and no dosage adjustment required in the elderly patient with renal impairment. Double-antibiotic therapy may be considered with more extensive lesions. Fluoroquinolone-resistant strains exist, so alternative therapy must be considered. Such alternative treatment includes antipseudomonal β-lactams, including piperacillin, combination piperacillin-tazobactam, ceftazidime, and cefepime. In some drug-resistant cases, use of cephalosporins and antipseudomonal penicillins in combination with debridement may be necessary. Rare complications of retropharyngeal abscesses are drained surgically. For *Aspergillus* species, voriconazole has been successful as first-line treatment and shown superiority to amphotericin B in a randomized trial. Despite these newer treatments, the mortality rate is still 10% to 20% and may be as high as 50% if treatment is delayed.

Hyperbaric oxygen therapy efficacy remains unproven and is rarely now used for refractory cases of malignant otitis externa. Recent studies suggest that facial cranial nerve involvement may be a marker for extension of disease but by itself not an adverse

TABLE 65.3 Antimicrobial Agents for Treatment of Malignant Otitis Externa

Antipseudomonal agents	Ciprofloxacin 400 mg IV every 8 h Levofloxacin 750 mg IV daily Ceftazidime 2 g IV every 8 h Cefepime 2 mg IV every 8 h
Antimicrobials for *Aspergillus* species	Voriconazole 4-6 mg/kg IV every 12 h Liposomal amphotericin B 5-7.5 mg/kg/d IV Amphotericin B + itraconazole 5 mg/kg/d + 600 mg oral daily

Abbreviation: IV, intravenous.

prognostic factor. If untreated or inadequately treated, malignant external otitis may result in osteomyelitis of the base of the skull, sigmoid sinus thrombosis, abscess formation, meningitis, and death.

OSTEOMYELITIS OF THE SKULL BASE

Osteomyelitis of the base of the skull is a rare complication of malignant external otitis, chronic mastoiditis, or paranasal sinus infection.

Epidemiology and Pathobiology

As with malignant otitis, the patients are usually elderly, diabetic, or immunocompromised. Osteomyelitis may occur in conjunction with otitis but usually appears weeks or months after starting antibiotics.

Clinical Manifestations

Symptoms include headache, otalgia, hearing loss, and otorrhea, but patients are frequently without fever. As the process spreads, cranial nerves may be affected, especially the VII and VIII nerves. Extension of skull base osteomyelitis to the jugular foramen or hypoglossal canal may affect cranial nerves IX to XII, leading to dysphagia. In advanced cases, spread to the petrous pyramid may affect III, IV, V, and VI cranial nerves to cause ocular palsies or trigeminal neuralgia.

Diagnosis

Laboratory abnormalities include a normal or slightly elevated white blood cell count and high ESR. In general, leukocytosis is not common and not useful to diagnosis and management. The use of thin-cut CT sections through the skull base and temporal bones to visualize bony involvement plays an important role in the diagnosis of osteomyelitis and in assessing extent of disease. However, because more than 30% of affected bone needs to be demineralized to appear eroded on CT, early disease may escape detection by CT.

An MRI is useful in delineating soft-tissue involvement but has not proved beneficial for initial diagnosis or determining efficacy of treatment for skull-base osteomyelitis. Technetium bone scanning is a sensitive indicator of osteomyelitis but is not helpful in determining resolution of disease. Technetium uptake is nonspecific and may be seen in a number of conditions such as infection, trauma, neoplasm, and postoperatively. Gallium 67 citrate scans may be useful in tracking resolution of disease over time. Neither bone nor gallium scans are useful in determining the exact extent of the infection. Unlike technetium 99m scans, gallium 67 scans return to normal sooner once the infection is resolved and can be useful to signal clearing of infection. *S aureus* is now the most common isolated organism in osteomyelitis. Other potential causative agents include *P aeruginosa*, *S epidermidis*, *Proteus*, *Salmonella*, *Mycobacterium*, *Aspergillus*, and *Candida*.

Management and Outcome

Therapy for osteomyelitis consists of intravenous administration of antibiotics, usually a combination of an antipseudomonal penicillin or cephalosporin. Ciprofloxacin, with its strong bone penetration, has been effective when used alone or with other antibiotics. Ceftazidime has bactericidal activity against *Pseudomonas* species and has been used successfully as monotherapy. The disease is usually extensive, and conservative management of skull-base osteomyelitis is still an extended course of therapy. In rare cases of *Aspergillus* osteomyelitis, surgical debridement with radical mastoidectomy is usually required, in addition to long-term antifungal therapy. Monthly gallium scans may help to determine the response and duration of antibiotic therapy. In refractory cases, hyperbaric oxygen has been used as adjuvant therapy. Antibiotics should be continued for at least 1 week after the gallium scan becomes normal. Duration of antibiotic therapy varies but is usually for at least 1 month and, in some cases, may extend up to 6 months after diagnosis. Follow-up gallium scans may be performed 1 week after completion of antibiotic therapy to detect early recurrence and at 3 months for late recurrence. Mortality rates of 40% have been reported, but with prolonged antibiotic therapy, complete cure may be achieved. Recurrences may manifest up to 1 year later; true cure is considered when the patient is disease-free for a year after the treatment is begun.

66 Other Bacterial Central Nervous System Infections and Toxins

Kyle J. Coleman

KEY POINTS

1. Rickettsial infections, such as spotted fever rickettsioses and typhus group rickettsiae, are transmitted by arthropods that cause various neurologic syndromes, including meningoencephalitis, and are treated with doxycycline.
2. Zoonoses are caused by animal-to-person transmission and can uncommonly induce neurologic symptoms following a preceding systemic illness.
3. Diphtheria, botulism, and tetanus are diseases induced by toxin-producing bacteria that leads to disruption of peripheral nerves or the neuromuscular junction.

INTRODUCTION

This chapter discusses the bacterial infections that are classified as rickettsial infections. Rickettsial infections are acquired from invertebrates such as ticks, mites, fleas, and lice. Zoonotic infections are acquired from vertebrates, typically mammals. Infections can also occur by human-to-human transmission. This chapter reviews the spotted fever rickettsioses (SFR), ehrlichiosis and anaplasmosis, typhus, Q fever, brucellosis, leptospirosis, cat-scratch disease (CSD), anthrax, Whipple disease, and bacterial toxins.

RICKETTSIAL INFECTIONS

Rickettsiae are a group of obligate, intracellular coccobacilli that are transmitted via arthropod vectors to humans, which serve as dead-end hosts. Tickborne rickettsial diseases in the United States include the spotted fever rickettsioses, ehrlichioses, and anaplasmosis (Table 66.1). These tickborne rickettsial diseases have all been associated with neurologic manifestations. The most common SFR is Rocky Mountain spotted fever (RMSF). Additional rickettsial diseases that are associated with neurologic manifestations include murine typhus, epidemic typhus, and scrub typhus, which are transmitted by fleas, lice, and mites, respectively (Table 66.2).

Spotted Fever Rickettsiosis

SFR is a closely related group of obligate intracellular, gram-negative bacteria that includes *Rickettsia rickettsii*, *Rickettsia parkeri*, and *Rickettsia* species 364D. By far, the most common of these is *R rickettsii*, which is the causative bacterium of RMSF. Most commonly transmitted by the American dog tick, *Dermacentor variabilis*, it is found in the eastern, central, and western regions of the United States. Less common tick vectors include the Rocky Mountain wood tick, *Dermacentor andersoni*, seen in the western United States, and the brown dog tick, *Rhipicephalus sanguineus*, which is an important vector in Arizona and along the U.S.-Mexico border. The larval and nymphal stages of *Dermacentor* species usually do

TABLE 66.1 Tickborne Rickettsial Diseases

Disease	Cutaneous Findings	Neurologic Features	Diagnosis	Treatment
Spotted fever rickettsioses	Maculopapular rash in most 2-4 d from fever onset that begins in the wrists and ankles and spreads to extremities and trunk; can become petechial and involve palms and soles with sparing of face	Meningoencephalitis, cranial neuropathies, ataxia, deafness, seizures, rigidity, and tremor	Indirect immunofluorescence assay (IFA), immunostaining of biopsied skin rash	Doxycycline
Human monocytic ehrlichiosis	One-third with maculopapular or petechial rash involving trunk and extremities; typically spares the palms, soles, and face	Meningitis, meningoencephalitis, seizures, and coma; cranial neuropathies rare	IFA, whole blood polymerase chain reaction (PCR), visualization of morulae in monocytes on Wright and Giemsa staining	Doxycycline
Human ewingii ehrlichiosis	Rarely seen	Meningitis or encephalitis uncommon	IFA, whole blood PCR	Doxycycline
Human granulocytic anaplasmosis	Rarely seen	Cranial nerve palsies, brachial plexopathies, and demyelinating polyneuropathies; meningitis or encephalitis uncommon	IFA, whole blood PCR, visualization of morulae in granulocytes on Wright and Giemsa staining	Doxycycline

TABLE 66.2 Typhus Group Rickettsiae and Scrub Typhus

Disease	Causative Organism	Vector	Cutaneous Findings	Neurologic Features	Diagnostic Tests	Treatment
Epidemic typhus	*Rickettsia prowazekii*	Lice	Eschar with associated edema and regional lymphadenopathy	Meningoencephalitis most common Cranial nerve palsies, cerebellitis, transverse myelitis, neuropsychiatric involvement less common	Indirect immunofluorescence assay (IFA), real-time polymerase chain reaction (PCR) of biopsied skin lesions	Doxycycline
Murine typhus	*Rickettsia typhi*	Flea	Erythematous and blanching macule that begins in the trunk. May spread to extremities but spares palms and soles; eschars absent	Headache most prevalent Meningitis or encephalitis rare	IFA, real-time PCR of biopsied skin lesions	Doxycycline
Scrub typhus	*Orientia tsutsugamushi*	Trombiculid mite (chigger)	Same as murine typhus	Coma and seizures in up to 80% Meningitis and encephalitis common	Serum: enzyme-linked immunosorbent assay, IFA CSF: PCR	Doxycycline

not bite humans, and the adult ticks have maximum activity during late spring through early summer. The principal hosts include deer, dogs, livestock, and rodents.

Epidemiology

The reported incidence of SFR in the United States has risen dramatically from approximately 500 cases in the year 2000 to greater than 6,000 cases in the year 2017. Although the disease has been reported in every state in the continental United States, there is a notable geographic preference (Fig. 66.1). Greater than 60% of cases can be found in one of five states: Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee. Men are twice as likely to be affected as women, and the highest incidence is found in ages 60 to 69 years, although the highest fatality rate is among children aged younger than 10 years old. Disease also has a seasonal preference with 90% occurring between the months of April and September.

Pathophysiology

After entry of rickettsiae into the epidermis following a tick bite, hematogenous dissemination occurs. There is a predilection for the endothelium of capillaries and arterioles, and the clinical manifestations are a direct result of the vascular inflammation. The most common organ affected is the skin. The heart, lungs, kidneys, spleen, and central nervous system (CNS) are also involved to varying degrees. Endothelial infection leads to a perivascular infiltrate composed of lymphocytes and macrophages. This increases vascular permeability with leakage of fluid into surrounding tissues. In the CNS, this can lead to cerebral edema and petechial hemorrhages. Occlusion of arterioles also commonly occurs with resultant microinfarctions.

Clinical Manifestations

Symptoms typically present 3 to 12 days after a tick bite, although only 50% to 60% of patients recall tick exposure. Some might describe a pruritic or erythematous lesion that they associate with a mosquito bite or other insect. The onset of symptoms is sudden and nonspecific and includes fever, chills, headache, and malaise. Abdominal pain, nausea or vomiting, anorexia, and delirium also commonly occur. A rash appears 2 to 4 days after fever onset and is initially a blanching, pink macule on the wrists and ankles. It quickly spreads centripetally to the arms and legs first, then to the trunk with sparing of the face. Over the next several days, the rash will become maculopapular with centralized petechiae. This will evolve into a generalized petechial rash that includes the palms and soles by days 5 to 6 (Fig. 66.2).

Neurologic manifestations are as high as 40% even when headache, the most common neurologic symptom, is excluded. Altered mental status is common and can range from irritability to decreased level of consciousness to coma in severe cases. Focal neurologic deficits are often transient in mild disease and include unilateral facial paresis, cranial nerve palsies, hemiparesis, and ataxia. In more severe forms of disease, progression to tremor, rigidity, deafness, and seizures occur. The most feared neurologic complication is encephalitis, which occurs in approximately 2%. Approximately 5% to 10% of patients with SFR meningoencephalitis will have permanent CNS dysfunction that includes cognitive impairment, hearing loss, weakness, dysarthria, and blindness. Other severe complications of SFR include myocarditis, cardiac dysrhythmias, and hepatic or renal injury, all of which are less frequent than neurologic involvement.

Diagnosis

Common serum laboratory tests are of variable importance. The white blood cell count will be normal or slightly elevated. Thrombocytopenia, mild elevations in hepatic transaminases, and hyponatremia are common in the mid to late stages of the disease, but platelet counts, liver function tests, and serum sodium are often normal in the early stages. Cerebrospinal fluid (CSF) testing is necessary when meningoencephalitis is suspected. A pleocytosis of white blood cells will be present (typically <100 cells/mm^3 total) with a lymphocytic predominance in most, although a neutrophilic predominance occurs in up to one-third. The protein concentration will be moderately elevated (100-200 mg/dL), and the glucose concentration is usually normal.

The majority will have abnormal neuroimaging findings. Brain magnetic resonance imaging (MRI) with gadolinium is the preferred modality. RMSF has a classic appearance on MRI known as the *starry sky* pattern (Fig. 66.3). This is caused by vasculitic

FIGURE 66.1 Map of reported incidence rate of spotted fever rickettsiosis, by county—United States, 2000-2013. (Photo/Centers for Disease Control and Prevention.)

changes resulting in subcortical and periventricular infarcts in a perivascular distribution. Within the appropriate clinical context, this finding strongly supports the diagnosis of SFR meningoencephalitis, particularly in children. However, its absence does not exclude the diagnosis, especially in adults. Other neuroimaging abnormalities of SFR include meningeal enhancement and nonspecific punctate abnormalities in the subcortical white matter and deep gray structures, such as the thalamus.

FIGURE 66.2 Late-stage petechial purpuric rash involving the sole of the foot in a patient with Rocky Mountain spotted fever. (Photo/Centers for Disease Control and Prevention.)

The most sensitive method of diagnosing SFR is via indirect immunofluorescence antibody assay using paired acute and convalescent sera. This method requires obtaining a serum sample as soon as the diagnosis is suspected, and immunoglobulin G (IgG) to rickettsial antigens is quantified. A second serum sample is obtained 2 to 4 weeks later. The diagnosis of SFR is confirmed if there is a fourfold or greater increase in antibody titers between the two samples. Testing of whole blood by polymerase chain reaction (PCR) is available for SFR but has a low sensitivity, although it is more likely to be positive if the disease is severe. Immunostaining of a skin biopsy obtained from a rash or eschar can provide a pathogen-specific diagnosis if the aforementioned methods are unrevealing.

Treatment and Outcome

Doxycycline is the treatment of choice for all tickborne rickettsial diseases regardless of age and should be started empirically if the diagnosis is suspected LEVEL 1. This includes children younger than 8 years old as the benefits of doxycycline far outweigh the risks. Recent studies with children younger than the age of 8 years who received doxycycline demonstrated no teeth or enamel abnormalities. Chloramphenicol is a potential alternative treatment for RMSF in pregnant women. The recommended dose of doxycycline is 100 mg twice a day for adults and 2.2 mg/kg body weight twice daily for children weighing <45 kg. Duration of treatment

FIGURE 66.3 Rocky Mountain spotted fever in pediatric patient with "starry-sky appearance." Diffusion-weighted magnetic resonance with apparent diffusion coefficient images. **A,B:** Diffusion-weighted magnetic resonance images at the same level as **Fig. 1** show multiple punctate foci of increased signal corresponding to the T2 white matter lesions. **C:** Corresponding apparent diffusion coefficient map confirms restricted diffusion. (From Crapp S, Harrar D, Strother M, Wushensky C, Pruthi S. Rocky Mountain spotted fever: 'starry sky' appearance with diffusion-weighted imaging in a child. *Pediatr Radiol.* 2011;42:499-502.)

is variable, although should be for a minimum of 5 to 7 days. The Centers for Disease Control and Prevention (CDC) recommends treatment for at least 3 days after the fever resolves and until clinical improvement is noted. Typical treatment duration is for 1 to 2 weeks.

Despite the dramatic decrease in fatality rates since the introduction of doxycycline, SFR remains the most deadly of the rickettsial diseases. Approximately 5% to 10% will die from the illness, with the remaining survivors experiencing permanent sequelae such as epilepsy, hearing loss, and cognitive impairment if meningoencephalitis developed.

Prevention is based on proactive measures. Persons should inspect themselves, their pets, and their children after spending time outdoors in woody or grassy areas. Common locations for tick attachment include the scalp, axillae, and groin. The belt line and areas under socks should be carefully inspected as well. Pets in general, and dogs in particular, should be inspected around and inside the ears. Bathing shortly after outdoor recreational activity has been shown to be an effective protective measure for tickborne diseases. Other preventative measures include tucking pants into socks, using permethrin coated clothing, and spraying skin with N,N-diethyl-meta-toluamide. If a tick is found, it should be carefully removed with tweezers with strict avoidance of the tick with other areas of the skin.

Ehrlichiosis and Anaplasmosis

Ehrlichiosis and anaplasmosis are diseases due to tick-borne, gram-negative, obligate intracellular bacteria that infect leukocytes that are part of the family *Anaplasmataceae*. The three predominant species in the United States are *Ehrlichia chaffeensis*, which causes human monocytic ehrlichiosis (HME); *Ehrlichia ewingii*, which causes human ewingii ehrlichiosis (HEE); and *Anaplasma phagocytophilum*, which causes human granulocytic anaplasmosis (HGA).

Epidemiology

Like other tick-borne diseases, such as SFR, infections are predominantly in the summer months. HME is transmitted by the lone star tick, *Amblyomma americanum*, acquiring it from its host, the white-tailed deer. Four states (Missouri, Arkansas, Virginia, and New York) account for the majority of reported cases and are known for woodland habitats with large white-tailed deer populations. HEE is also transmitted by the lone star tick but occurs at a much lower frequency than HME, and the reported cases are mainly confined to Missouri. Anaplasmosis is transmitted by the species *Ixodes*, the same tick that transmits Lyme disease and coinfection is possible. *Ixodes scapularis* transmits HGA in the northeast and midwest United States, whereas *Ixodes pacificus* is the primary vector on the west coast.

The incidence of ehrlichiosis and anaplasmosis is on the rise. The incidence of HME has risen over eightfold since the start of the century with a total incidence of approximately 1,700 cases in 2017. HGA has increased nearly sixfold in the past decade with approximately 6,000 cases in 2017. HEE continues to remain much less common with approximately 200 total cases in the past decade. Like SFR, ehrlichiosis and anaplasmosis has a predominance of infections in males and adults older than 60 years of age.

Pathophysiology

E chaffeensis infects monocytes and macrophages where the organism will multiply and form packed clusters of bacteria called *morulae*. In a similar way, *E ewingii* and *A phagocytophilum* infect granulocytes. The greatest distribution of bacteria is found where these cells typically reside: the spleen, lymph nodes, and bone marrow. The resulting damage is caused by a systemic inflammatory response rather than the direct endothelial injury observed in SFR, making vasculitis rare in ehrlichiosis and anaplasmosis.

Clinical Manifestations

Symptoms of ehrlichiosis and anaplasmosis develop 5 to 14 days after a tick bite beginning with a nonspecific illness with fever, headache, malaise, and myalgia. A rash, which characterizes SFR, is much less common. In HME, about one-third will develop a maculopapular or petechial rash 5 days after illness onset that will involve the extremities and trunk but often spare the palms, soles, and face. A rash is rarely seen with HEE or HGA.

CNS complications are most likely to occur in HME with at least 20% developing an isolated meningitis or meningoencephalitis. Seizures and coma are commonly reported complications with cranial nerve palsies being rare. CNS involvement is uncommon in HGA with meningitis or encephalitis reported in approximately 1% of cases. In contrast to HME, peripheral nervous system involvement is more common with cranial nerve palsies, brachial plexopathies, and demyelinating polyneuropathies all reported with HGA. Although HEE has been associated with meningitis, the frequency of neurologic complications is currently unknown.

Diagnosis

Diagnosis of ehrlichiosis and anaplasmosis can be difficult given the nonspecific symptoms reported. A high degree of suspicion should be kept for reported tick exposure or time spent outdoors in endemic regions. Standard blood laboratory tests are useful. Leukopenia, thrombocytopenia, and elevated transaminases are present in the majority of patients. Wright and Giemsa staining can allow for visualization of morulae in monocytes and granulocytes on peripheral smear (Fig. 66.4). Whole blood PCR, which has a low sensitivity in SFR, allows for rapid detection in up to 85% in the acute stages of the illness. CSF analysis is most useful in HME and usually demonstrates a lymphocytic pleocytosis (<100 cells), normal glucose concentration, and mildly elevated protein concentration. MRI with gadolinium may demonstrate leptomeningeal enhancement in those with suspected meningoencephalitis.

Despite the usefulness of the aforementioned tests, serologic testing remains the standard for diagnostic confirmation. Like SFR, fourfold or greater rise in antibody titers between acute and convalescent serum samples drawn 2 to 4 weeks apart with IFA IgG testing is required. In those with a rash, skin biopsy with immunostaining is another option for diagnostic confirmation with a high sensitivity.

Treatment and Outcome

The recommended treatment and duration for ehrlichiosis is the same as for SFR. Doxycycline in both adults and children should be used until 3 days after fever dissipation and until evidence of clinical improvement. The CDC recommends that anaplasmosis also be treated with doxycycline but for a longer minimum of 10 days given the possibility of coinfection with Lyme disease LEVEL 1. For pregnant women and those with a tetracycline allergy, rifampin 300 mg twice daily is an alternative therapy. The outcomes are very good in HEE and HGA with fatalities being rare. Death is more common with HME but, at 3%, is still less than SFR.

Scrub Typhus

Scrub typhus is a rickettsial infection caused by the bacterium *Orientia tsutsugamushi*. Transmission to humans requires a bite from the larval stage of the trombiculid mite (chigger). Because chiggers prefer areas of heavy vegetation and torrential downpours, scrub typhus is largely confined to rural areas of Asia and islands in the Pacific. It is extremely uncommon in North America, but infection can be acquired in travelers to endemic areas.

Clinical Manifestations

The disease occurs 1 to 3 weeks following a chigger bite. In the early stages, fever and headache are invariably present, and conjunctival injection and gastrointestinal symptoms are common. By day 5 of the illness, the majority will demonstrate an eschar at the site of the chigger bite with an associated

FIGURE 66.4 Wright stain of peripheral blood smears showing an intramonocytic morula associated with *Ehrlichia chaffeensis* infection (**left**) and an intragranulocytic morula (**right**), such as associated with *Ehrlichia ewingii* or *Anaplasma phagocytophilum* infection. (Photos/J. Stephen Dumler, University of Maryland [left]; Bobbi S. Pritt, Mayo Clinic [right].)

regional lymphadenopathy. The eschar contains a high bacterial load, which allows *O tsutsugamushi* to invade peripheral endothelial cells and spread through the blood and lymphatic systems. The result is a systemic vasculitis with potential involvement of the heart, lungs, liver, spleen, and CNS.

When the CNS is involved, a multitude of potential complications may arise. Meningoencephalitis is by far the most common complication and may occur in up to two-thirds of patients with scrub typhus. In these patients, status epilepticus is frequent. Additional neurologic manifestations are protean, but include cranial nerve palsies, cerebellitis, transverse myelitis, peripheral nervous system involvement, and neuropsychiatric involvement that include visual hallucinations.

Diagnosis

The diagnosis of scrub typhus is supported by the clinical presentation along with a history of residing or traveling to known endemic areas. The presence of one or more eschars is particularly helpful, but given an eschar is not present in all patients, serology becomes paramount. The gold standard for diagnosis is the indirect immunofluorescence assay (IFA). However, IFA has numerous limitations including its expense and the possibility for false-negative results early in the disease course. Enzyme-linked immunosorbent assay (ELISA) is the most practical test given its ease of use, ability to detect immunoglobulin M (IgM) antibodies early in the disease course, and sensitivity and specificity greater than 90%, respectively.

For those with meningoencephalitis, CSF analysis reveals a mononuclear pleocytosis and an elevated protein concentration. Hypoglycorrhachia may be seen in up to one-fourth with the remainder having a normal CSF glucose concentration. Neuroimaging is unrevealing in the vast majority. PCR testing of the CSF is available, although its reliability is unknown.

Treatment and Outcome

Scrub typhus responds exquisitely to antibiotic therapy and improvement is seen within 48 hours of treatment, even in meningoencephalitis. Given its relationship to other rickettsial organisms, doxycycline remains the antibiotic of choice. Alternatives include azithromycin and rifampicin, which have a similar efficacy to doxycycline. For those who travel to endemic areas, preventative measures should be undertaken. This includes using an appropriate insect repellant, such as N,N-diethyl-meta-toluamide, permethrin-infused clothing, and possibly chemoprophylaxis with a weekly dose of doxycycline.

Typhus Group Rickettsiae

The two most prominent illnesses of the typhus group rickettsiae (TGR) are epidemic typhus and murine typhus. The causative agent of epidemic typhus is *Rickettsia prowazekii*. The organism is transmitted through the feces of *Pediculus humanis corporis*, a body louse. In contrast, murine typhus is caused by *Rickettsia typhi* and is transmitted to humans by the rat flea, *Xenopsylla cheopis*. The flea acquires the bacterium by feeding on rat's blood and excretes the organism in its feces onto human skin. For both epidemic and murine typhus, humans become infected after rubbing or scratching skin that contains the feces.

Epidemiology

Epidemics of TGR still occur frequently throughout the world. Although several thousand cases occurred yearly in the United States in the first part of the 20th century, epidemic typhus is rarely seen today. Epidemic typhus occurs in crowded, unsanitary conditions where lice outbreaks can occur such as prisons, refugee camps, and areas of extreme poverty. Sporadic cases have been associated with the flying squirrel. Murine typhus, given its spread by fleas, prefers warmer climates and coastal regions with a recent increase in reported cases in California and Texas. Like other rickettsial infections, murine typhus has a predilection for the summer months.

Clinical Manifestations

Like SFR, systemic and neurologic symptoms of TGR arise from rickettsiae infecting endothelial cells, resulting in a vasculitis. Multiple organs are affected with the lungs and brain being the most prominent. Other organs variably affected include the heart, liver, and kidneys. The incubation period is 1 to 2 weeks, and the illness starts with 1 to 3 days of generalized malaise followed by the abrupt onset of high fever and severe headache. In a large proportion, primary involvement of the lungs with a resultant pneumonia is common. A relapsing form of epidemic typhus, Brill-Zinsser disease, occurs years to decades after an initial attack. It is believed that the rickettsiae remain dormant in macrophages until a subsequent reactivation occurs. The symptoms that arise in Brill-Zinsser are similar to the first attack but generally milder in comparison.

A rash, appearing as an erythematous and blanching macule initially, is common with TGR but still less so than in SFR. Other skin lesions, such as petechiae and purpura are seen in up to one-third, but eschars are notably absent. Also in contrast to SFR, the rash begins in the trunk and axilla and either remains localized or spreads centrifugally to the extremities with sparing of the palms and soles.

When compared to epidemic typhus, murine typhus is much less concerning. Its signs and symptoms, although similar to epidemic typhus, occur with a more gradual onset and a less severe intensity. Neurologic abnormalities beyond headache are uncommon, and meningitis or encephalitis is rare. In epidemic typhus, CNS complications such as coma, delirium, and seizures occur in up to 80%. Meningoencephalitis is a complication of epidemic typhus with hearing loss being a common sequela.

Diagnosis

Serology remains the standard diagnostic test for TGR. Like other rickettsial infections, IFA is the best method for diagnosis. A fourfold rise in IgG antibody titers between acute and convalescent sera taken 2 to 4 weeks apart is necessary for confirmation. Real-time PCR of skin lesions is available, but its reliability is dependent on the bacterial number present in the biopsied tissue. CSF analysis, most likely performed in epidemic typhus, shows mononuclear pleocytosis, elevated protein concentration, and normal glucose concentration and helps to support suspicion of CNS involvement.

Treatment and Outcome

Doxycycline is the treatment of choice for TGR. The recommendations for duration of treatment are the same as SFR. In epidemic typhus, delousing is necessary to prevent spread of infection or reinfection. If appropriate antimicrobial treatment and duration is given for epidemic typhus, the mortality rate is approximately 4%. Complications of vascular compromise, including gangrene of distal fingers and toes, have been reported. In murine typhus, complete recovery is the general expectation, even in the absence of antimicrobial therapy.

ZOONOTIC INFECTIONS

Zoonoses are infections acquired by humans from other animals, usually mammals. These infections are found worldwide and are often observed in rural, agricultural communities where infected livestock are prevalent. In addition, poor hygiene or sanitation can contribute to the spread of these diseases. Although zoonotic infections are common throughout many regions of the world, they are usually rare in the United States and often confined to travelers to endemic regions. A summary of zoonoses can be found in Table 66.3.

Q Fever

Q fever is caused by *Coxiella burnetti*, a gram-negative, obligate intracellular pathogen. Its primary reservoirs are livestock. Infection typically occurs by inhaling aerosolized particles from placental products. Importantly, Q fever has both an acute and a chronic phase. It is considered a rickettsial-like organism and responds well to tetracyclines.

Epidemiology

Infection with *Coxiella* occurs throughout the world. The primary reservoirs are sheep, cattle, and goats, which are typically asymptomatic. As a result, Q fever is most commonly seen in rural and agricultural regions and in persons who have direct contact with these animals, such as veterinarians, farm workers, and butchers. The most common mode of transmission is inhalation of aerosolized particles from placental tissue and fluids. As *Coxiella* is resistant to most physical forces, it can survive for months to years. Dust contaminated with placental products can travel by wind and infect those miles from the initial source. Q fever can also be obtained through ingestion of unpasteurized dairy products as *Coxiella* can be shed in the milk of infected animals. Other modes of transmission, such as human-to-human contact, acquisition from blood transfusions or bone marrow transplantation from infected donors, or an infected tick bite, are extremely rare.

Clinical Manifestations

There are two recognized forms of *Coxiella* infection in humans: acute Q fever and chronic Q fever. In the acute form, half of infected individuals are asymptomatic. In symptomatic patients, acute Q fever is typically characterized by a self-limited, nonspecific febrile illness that begins 2 to 3 weeks following inhalation or ingestion. Pneumonia is commonly seen and results from aerosolized organisms proliferating in the lungs. Hepatitis may also be seen, particularly in those infected as a result of ingestion of contaminated dairy products.

A severe headache is the most common neurologic manifestation and is almost always seen with Q fever. As a result, lumbar

TABLE 66.3 Zoonoses

Disease	Causative Agent	Reservoirs	Systemic Features	Neurologic Features	Diagnostic Tests	Treatment
Q Fever	*Coxiella burnetti*	Sheep, cattle, and goats	Acute: pneumonia most common, hepatitis Chronic: endocarditis, osteomyelitis, hepatitis	Meningitis or encephalitis in 1%-2%	Serum: immunofluorescence assay Cerebrospinal fluid (CSF): polymerase chain reaction (PCR)	Doxycycline
Brucellosis	*Brucella melitensis, Brucella abortus, Brucella suis*	Goats, sheep, cattle, and pigs	Intermittent and chronic fever, migratory arthralgias, spondylitis, hepatitis, and orchitis	Isolated meningitis or meningoencephalitis most common; cranial neuropathies, myelitis, epidural abscess	Serum: serum agglutination test, enzyme-linked immunosorbent assay (ELISA) CSF: Test agglutination with Coombs test.	Systemic disease: doxycycline and rifampin Neurobrucellosis: doxycycline, rifampin, and ceftriaxone
Leptospirosis	*Leptospira*	Rodents	Nonspecific febrile illness, uveitis, conjunctival suffusion, headache Later, cardiac arrhythmias, pulmonary disease, renal failure, jaundice, and bleeding diathesis	Meningitis most common; Guillain-Barré syndrome, myelopathy, encephalitis, subarachnoid hemorrhage, and cranial neuropathies	Serum: microscopic agglutination test (MAT), ELISA, PCR CSF: PCR	Septicemic phase: doxycycline Immune phase: penicillin or ceftriaxone
Cat-scratch disease	*Bartonella henselae*	Cats	Erythematous papules or pustules at site of infection; painful lymphadenopathy proximal to skin lesions	Encephalitis, neuroretinitis, hemiparesis, cranial neuropathies, infectious myelitis, Guillain-Barré syndrome	Serum: immunofluorescence assay, ELISA Biopsy: PCR of lymph node aspirates CSF: PCR	Azithromycin
Anthrax	*Bacillus anthracis*	Goats, sheep, and cattle	Cutaneous: pruritic and painless papule that evolves into a black eschar Ingestion: sore throat, dysphagia, diarrhea Inhalation: fever, chills, cough, shortness of breath Injection: soft tissue infection	Rapidly progressive and highly fatal hemorrhagic meningitis	Serum: ELISA, PCR Culture: blood, pleural fluid, nasal swab	Uncomplicated: ciprofloxacin or doxycycline Meningitis: ciprofloxacin, meropenem, and linezolid

puncture is typically performed to exclude meningitis, although either meningitis or encephalitis is found in no more than 1% to 2% of patients.

Chronic Q fever is seen months to decades following an acute infection, even if asymptomatic. In adults, a culture-negative endocarditis of the native valve or infection of vascular prostheses is the most common manifestation and is fatal if left untreated. Chronic pulmonary infections, osteomyelitis, and chronic hepatitis are possible but less common. In the pediatric population, a relapsing osteomyelitis is frequently seen. Despite the severe manifestations of chronic disease, it arises in less than 5%.

Diagnosis

Q fever is best diagnosed by serology with IFA. Interpretation of this serology is dependent on the understanding of the two antigenic phases of *C burnetii*. In acute infection, phase II antibodies to *Coxiella* appear first and in higher titers than phase I antibodies. Diagnosis of acute infection is made by demonstrating a fourfold or greater rise in phase II IgG antibodies between acute and convalescent sera collected 3 to 6 weeks apart. Use of whole blood PCR in the first week of the illness, prior to seroconversion, is useful in diagnosis if positive but lacks sensitivity because the sample is dependent on bacterial load. Phase I antibodies are associated with persistent infection, although they almost never exceed phase II antibodies in quantity. High titers of phase I antibodies that continue to rise months to years following acute infection correlate with the development of endocarditis and other chronic Q fever presentations.

Meningitis or encephalitis is supported by the presence of a lymphocytic pleocytosis, elevated protein concentration, and normal glucose concentration on CSF testing, although these findings are only variably seen. PCR of CSF is available with a high specificity but can be falsely negative. Neuroimaging is generally normal.

Treatment and Outcome

The majority of acute Q fever cases resolve spontaneously within a few weeks, even without antimicrobial therapy. Although treatment is not routinely recommended for asymptomatic individuals, chronic Q fever might still occur. The recommendation for treatment of acute Q fever is doxycycline, and its maximum effect is achieved if initiated within 3 days of symptom onset. Alternative antibiotics include moxifloxacin, clarithromycin, and rifampin if a tetracycline allergy exists. Prevention with an inactivated, whole-cell vaccine (Q-Vax) is available for those in high-risk professions or in highly endemic regions. Neurologic sequelae are rare but hemiparesis, paresthesias, and peripheral neuropathies have been reported.

The treatment of chronic Q fever is a greater challenge. A combination of doxycycline 100 mg twice daily and hydroxychloroquine 200 mg 3 times daily for a minimum of 18 months for native valve infections, and 24 months for prosthetic valve infections, is recommended by the CDC LEVEL 1. Monthly serologic testing of phase I and II IgG/IgM antibodies to *Coxiella* are performed to ensure treatment response. Even after treatment completion, serology should be checked twice yearly for a minimum of 5 years.

Brucellosis

Brucellosis is a common zoonotic disease present throughout the world with several highly endemic areas interspersed. It is acquired by a gram-negative, facultative intracellular, coccobacilli termed *Brucella*. Transmission requires direct contact with infected animals, consumption of unpasteurized dairy products, or airborne particles.

Epidemiology

The Mediterranean and the Middle East have traditionally been the highest risk regions. Other highly endemic regions include South and Central America, the Caribbean, Eastern Europe, Asia, and Africa. *Brucella melitensis* is the most likely species to cause human infection and usually affects goats or sheep, whereas *Brucella abortus* and *Brucella suis* are the causative organisms that infect cattle and pigs, respectively. The majority of cases in humans are acquired after consumption of unpasteurized dairy products. Direct contact with infected animals as seen in farmers, veterinarians, or butchers are observed in a sizable minority. Rarely, inhalation of aerosolized particles or direct inoculation of an open wound can account for infection.

Clinical Manifestations

Brucellosis classically presents with an acute febrile illness that coexists with other constitutional symptoms such as chills, malaise, anorexia, and headache. Fever is often irregular and intermittent and, along with malodorous perspiration, can be highly suggestive of brucellosis. Migratory arthralgias, myalgias, and severe back pain with spondylitis are common and can be debilitating. Abdominal pain with associated hepatosplenomegaly is seen in up to one-fourth of patients. These symptoms can persist for weeks or months. A chronic form, which is often relapsing, exists in a smaller number of patients with endocarditis, orchitis, and chronic fatigue being frequent complications. Given its protean manifestations, essentially any organ system can be affected and a detailed history, which includes travel and occupational history, is mandatory.

Neurologic complications can be seen in approximately 5%. The most frequent neurologic manifestation is an isolated meningitis or meningoencephalitis. The chief complaint will be a severe, unrelenting headache that may persist for weeks to months prior to presentation. Cranial neuropathies are frequent with resultant sensorineural hearing loss, facial weakness, or diplopia. Neuropsychiatric manifestations and seizures are common with encephalitis or brain abscess. Myelopathy may be seen in up to 10% of neurobrucellosis cases and can be due directly from an acute or postinfectious myelitis or indirectly due to spinal cord compression from epidural abscess or spondylitis.

Diagnosis

Although isolation of *Brucella* on culture from blood or other infected organ system is considered the gold standard, it is often negative. Real-time PCR with its ability to give reliable results in as little as 30 minutes is likely the best test, although it is often unavailable in endemic regions. Serologic methods with serum agglutination test (SAT) or ELISA are the standard modalities for diagnosis given their cost-effectiveness. SAT works by measuring antibody production against known *Brucella* lipopolysaccharides.

In neurobrucellosis, CSF analysis typically demonstrates a mononuclear pleocytosis, elevated protein concentration, and low glucose concentration. *Brucella* test agglutination with Coombs test in CSF has a high sensitivity and specificity, and with a titer of 1:8 or greater, secures the diagnosis. Neuroimaging may be abnormal with leptomeningeal enhancement, white matter involvement, brain abscess, or cerebral edema being the most likely findings.

Treatment and Outcome

Antibiotic treatment with a combination of doxycycline and rifampin for at least 6 weeks is expected. Neurobrucellosis requires either a combination of doxycycline and an aminoglycoside or triple therapy with doxycycline, rifampin, and ceftriaxone. Proposed regimens range from 4 to 6 months or until resolution of CSF abnormalities. A short course of adjunctive corticosteroids is often used with myelitis.

Mortality is less than 1%, with endocarditis being the most likely cause of death. The prognosis of neurobrucellosis is good especially if an isolated meningitis, and residual neurologic deficits are uncommon. Deficits that may persist include irreversible hearing impairment, and weakness when myelopathy is present. Preventative measures include hygiene education for farmers and other workers with animals, preparation and treatment of unpasteurized dairy products, and development of human vaccines in highly endemic regions.

Leptospirosis

Leptospirosis is a common and underdiagnosed zoonotic infection caused by the obligate, aerobic spirochete, *Leptospira*. Humans obtain the organism after contact with water contaminated by the urine of infected animals. Although typically self-limited, it can lead to serious complications involving the renal, hepatic, and neurologic systems.

Epidemiology

Although present worldwide, leptospirosis has a predilection for tropical climates in parts of Asia, the Caribbean, Africa, and Latin America. In the United States, there are 100 to 200 cases most years. The peak incidence is during the summer and fall months. Rodents, most notably rats, are important hosts for the spread of human disease. An infected rat can be asymptomatic its entire life with the spirochete surviving long-term in the renal tubules and being shed continually in the urine. *Leptospira* can survive for weeks in the soil in warm weather where it comes in contact with humans. Epidemics are associated with flooding or heavy rainfall in endemic areas with poor sanitation and housing conditions. Travelers who engage in recreational, freshwater activities such as swimming or boating, particularly after flooding or heavy rainfall, are at increased risk.

Clinical Manifestations

The majority of infections are asymptomatic. If clinical symptoms do occur, they begin typically 1 to 2 weeks following exposure. Approximately 90% of symptomatic patients will experience a self-limited febrile illness characterized by fever, severe headaches, nausea, vomiting, and myalgias that classically involve the calves and back. Ocular abnormalities can also be common and include conjunctival suffusion or uveitis. The most common neurologic manifestations during this stage are headache, altered mentation, and meningismus. This first phase is known as the *septicemic* (or anicteric) *phase* and lasts for about 1 week.

After cessation of the fever, and the end of the septicemic phase, there is a recurrence of the illness after a 1 to 3 day interval in 5% to 10%. This second immune (or icteric) phase is associated with the development of antibodies and leads to severe systemic manifestations. Cardiac arrhythmias and pulmonary disease including hemorrhages can be seen. Weil syndrome may occur during this time and has a classic triad of jaundice, renal failure, and bleeding diathesis. During the immune phase, involvement of the CNS occurs in up to 25%. Meningitis, with or without systemic symptoms, is the most common manifestation. Other less common neurologic complications include cranial neuropathies, Guillain-Barré syndrome (GBS), myelopathy, encephalitis, and subarachnoid hemorrhage.

Diagnosis

The gold standard for diagnosis is by serology using the microscopic agglutination test comparing acute and convalescent serum samples. However, microscopic agglutination test is not widely available. ELISA has an extremely high sensitivity and specificity and is more readily available. Real-time PCR can detect *Leptospira* accurately in the blood and CSF during the septicemic phase and in the urine during the immune phase. CSF analysis reveals elevated intracranial pressure and elevated protein concentration. A lymphocytic pleocytosis is usually observed but may be neutrophilic early in the course. CSF glucose concentration is usually normal but can be slightly decreased in one-third.

Treatment and Outcome

Doxycycline 100 mg twice daily is the antibiotic of choice for the septicemic phase and should be started empirically if the disease is suspected. For alternatives to tetracyclines, amoxicillin and ampicillin are alternatives. For those presenting in the immune phase, including those with meningitis, intravenous penicillin or ceftriaxone should be given. Treatment duration is generally 5 to 7 days. The overall outcomes are excellent in most. In Weil syndrome, the fatality rate is the highest (5%-10%), and is typically from acute renal failure, pulmonary hemorrhage, or cardiovascular collapse. Most neurologic complications resolve without sequelae.

Prevention is based on controlling the spread of leptospirosis. This includes avoiding stagnant water and runoff from farms, rodent control, and vaccination of livestock. Chemoprophylaxis with doxycycline in people at high risk for exposure can be considered, although no strong recommendations exist.

Cat-Scratch Disease

CSD is a zoonotic disease primarily transmitted to humans by a gram-negative bacterium, *Bartonella henselae*. The disease is spread among felines by the cat flea, *Ctenocephalides felis*, and is ultimately spread to humans by the scratches and bites of cats, particularly kittens.

Epidemiology

CSD is distributed worldwide and is a nonepidemic disease. In the United States, the highest incidence of the disease is found in children younger than 14 years of age and in the southern states. There is a seasonal predilection from August to January, and females are more likely than males to be infected. At least 90% of cases will report cat exposure in the preceding 2 weeks, and the majority will be able to identify the site of the cat scratch or bite. Infected cats do not display manifestations of the disease, and it is likely that a large proportion of infected individuals will remain asymptomatic.

Clinical Manifestations

The symptoms of CSD arise approximately 1 week following inoculation with the appearance of erythematous papules or pustules at the site of the cat scratch or bite. The predominant

feature of CSD, painful lymphadenopathy, will develop proximal to the papule or pustule 1 to 3 weeks later. Infected lymph nodes are commonly located in the axilla, inguinal, and neck regions and have associated erythema and induration. The lymphadenopathy will spontaneously resolve within 2 to 4 months.

Systemic symptoms do develop in the majority but are generally mild. A self-resolving low-grade fever develops in up to one-half. Follicular conjunctivitis is a common ocular finding. Additional nonspecific symptoms occur less frequently and include fatigue, nausea and vomiting, malaise, and headache. Severe manifestations such as endocarditis or osteomyelitis are rare. Bacillary angiomatosis can be seen in those with severe immunosuppression (eg, AIDS) and is characterized by red papules or nodules that are present on or under the skin. It can spread to other organs including the brain, bone, spleen, and liver. Biopsy is often necessary to distinguish it from Kaposi sarcoma.

Neurologic involvement in CSD is uncommon. Neuroretinitis, an optic neuropathy with an associated macular exudate referred to as a *macular star*, is an entity most commonly seen in CSD, and its presence can aid in the diagnosis (Fig. 66.5).

Encephalitis characterized by lethargy or combative behavior, variable focal neurologic deficits that include hemiparesis or cranial neuropathies, and seizures can occur. The encephalitis typically resolves without sequelae. Other less common neurologic syndromes include an infectious myelitis and GBS.

Diagnosis

Diagnosis is often made clinically based on a combination of a history of recent cat exposure along with physical examination findings of papules and tender lymphadenopathy. This alone is sufficient for beginning treatment. Serology can be useful in atypical cases, or if the diagnosis is unclear, and uses IFA with a fourfold or greater rise in antibody titers between acute and convalescent serum samples taken 6 weeks apart. The best test is likely the IgM capture-based ELISA, which has an extremely high sensitivity and specificity. If the diagnosis is still unclear, PCR or culture of lymph node aspirates is necessary to both confirm the diagnosis and exclude a mimicker such as neoplasm.

CSF analysis in encephalitis will show a mild lymphocytic pleocytosis, mildly elevated protein concentration, and normal glucose concentration. PCR to detect *Bartonella* in CSF is available. Neuroimaging is usually normal and, if abnormalities do exist, are often transient.

FIGURE 66.5 Neuroretinitis with severe swelling of the optic nerve and associated macular exudates ("macular star"). (From Holdeman NR, Ma L, Tang RA. Cat scratch neuroretinitis. *Int J Ophthalmol Clin Res.* 2017;4:71.)

Treatment and Outcome

Most patients with CSD recover without the need for antibiotics, although they may shorten the length of the disease. Multiple antibiotics have shown efficacy but azithromycin is the most commonly used. In adults, the CDC recommends azithromycin 500 mg on day 1 followed by 250 mg daily for 4 additional days LEVEL 4. For suppurative lymph nodes, aspiration is suggested, although incision and drainage should be avoided given the potential complication of fistula formation. Treatment of neurologic disease is largely supportive and most recover fully.

Anthrax

A zoonotic disease caused by a gram-positive and spore-forming bacterium, *Bacillus anthracis*, anthrax can arise in several distinct ways. Of these, the cutaneous route is the most prevalent with inhalation, injection, and intestinal modes being additional forms of infection. Hemorrhagic meningoencephalitis that is rapidly progressive and fatal is a distinguishing feature of anthrax.

Epidemiology

B anthracis primarily infects livestock such as goats, sheep, and cattle who acquire the bacterium by ingesting vegetation or from contaminated soil or water. Humans are incidental hosts and can become infected from consumption or contact with animal products or the environment. Anthrax is present in agricultural regions in Asia, South America, Sub-Saharan Africa, and eastern Europe. In the United States, outbreaks in livestock still occur, although human infection is rare.

Clinical Manifestations

There are four main clinical presentations. The first, cutaneous anthrax, accounts for greater than 95% of all human anthrax cases. Cutaneous anthrax begins within a week after exposure to infected animals or animal products, usually through an abrasion in the skin. The site becomes pruritic and a painless papule develops shortly after. The papule will enlarge, evolve into a vesicular lesion with serosanguineous fluid, and then ulcerate over 7 to 10 days, ultimately becoming a painless, black eschar (Fig. 66.6). Edema around the site and regional lymphadenopathy is typical.

The second clinical presentation, ingestion anthrax, develops within a week after consumption of contaminated animal products. The disease begins with fever and chills and will subdivide into two types. The oropharyngeal type is characterized by sore throat and dysphagia with airway compromise possible, whereas the intestinal type is characterized by nausea, vomiting, and bloody diarrhea. Altered mentation with cardiovascular arrest and death occurs within 5 days in over a third of both types.

The third clinical presentation, injection anthrax, occurs in intravenous drug users beginning with the development of a

FIGURE 66.6 Cutaneous anthrax. (**A** from Esfandbod M, Malekpour M. Cutaneous anthrax. *N Engl J Med*. 2009;361:178. **B** from Public Health Image Library.)

soft tissue infection at the site of injection that can spread hematogenously. This form is primarily seen with heroin users in Europe. The fourth clinical presentation is inhalation anthrax that begins with fever, chills, malaise, cough, and shortness of breath. It can be difficult to distinguish from pneumonia or influenza in the early stages. This will evolve over several days with the addition of altered mentation and headache. Inhalation anthrax has special interest given its association with bioterrorism but is rare.

Anthrax meningoencephalitis develops as the result of hematogenous spread from any of the four clinical forms or can occur in isolation. It generally presents with high fever, headache, vomiting, confusion, or agitation and progresses rapidly to coma with decerebrate posturing. Other clinical findings include myoclonus, focal or generalized seizures, and generalized rigidity. A pathologic feature of neurologic involvement is extensive hemorrhage of the leptomeninges, and hemorrhagic meningitis should raise suspicion for anthrax.

Diagnosis

Treatment should never be delayed while awaiting the return of diagnostic tests if anthrax is suspected. Clinical history in combination with exam findings, particularly if exposure to potentially infected animals or travel to endemic areas, is usually sufficient. In cutaneous anthrax, the black eschar is highly suggestive of the disease. In inhalational anthrax, chest radiographs often demonstrate a widened mediastinum and pleural effusions. Multiple serum tests exist for confirmation of the diagnosis of anthrax. This includes ELISA, serology comparing acute and convalescent serum samples 1 week apart, and PCR. Anthrax can also be diagnosed by blood culture, culture of pleural fluid, and nasal swab.

In meningoencephalitis, the CSF is grossly abnormal with a large neutrophilic pleocytosis (500-5,000 cells), elevated protein concentration, and low glucose concentration. The CSF itself will range from yellowish or pinkish in color to grossly bloody, and the supernatant frequently demonstrates xanthochromia. CSF culture shows large gram-positive rods singly or in chains. Neuroimaging is useful and demonstrates intracerebral, subarachnoid, or intraventricular hemorrhages.

Treatment and Outcome

For uncomplicated cutaneous anthrax, 7 to 10 days of oral ciprofloxacin or doxycycline is sufficient. For other forms of anthrax, with or without meningoencephalitis, triple therapy with intravenous ciprofloxacin, meropenem, and linezolid is recommended. The duration is at least 2 at 3 weeks or until clinical stabilization, whichever is longer. For inhalation anthrax, the duration should be extended to 60 days.

Outcomes are dependent on the anthrax type. Cutaneous anthrax has a mortality rate of less than 2% in treated persons. Ingestion, injection, and inhalation anthrax have mortality rates between 25% and 50% when treated. In meningoencephalitis, most cases are fatal with two-thirds dying within 24 hours of presentation. As most cases are uncomplicated cutaneous anthrax, sequelae are uncommon overall.

DISEASES OF HUMAN-TO-HUMAN TRANSMISSION

Human-to-human transmission is a common mechanism for the spread of disease. Represented in this section is Whipple disease, which is a rare entity with many neurologic manifestations, and mycoplasma pneumonia, which is a very common entity with rare neurologic complications.

Whipple Disease

Caused by the gram-positive bacterium *Tropheryma whipplei*, Whipple disease is a rare entity with diverse and chronic complications. Although classically affecting the gastrointestinal and musculoskeletal systems, any additional organ may be affected with neurologic disease being extremely common. Whipple disease remains a diagnostic and treatment challenge for practitioners.

Epidemiology

Although *T whipplei* has caused disease worldwide, the number of total cases reported is approximately 1,000. Humans are the

only known host of *T whipplei*, and the mode of transmission is believed to be through human-to-human contact. How humans acquire the organism is not completely understood. One possible mechanism of infection is through contaminated soil or water, and the bacterium has been detected in both saliva and stool samples of healthy controls.

Clinical Manifestations

The disease is characterized by two stages: a prodromal stage and a steady-state stage. The prodromal stage can be marked by many symptoms, although migratory polyarthritis and arthralgias tend to predominate. The steady-state stage manifests as weight loss and diarrhea. The duration between the prodromal and steady-state stages is 6 years on average, but this can be shortened by the use of immunosuppressive drugs. Cardiac involvement is common with pericarditis, and culture-negative endocarditis is also associated with the disease.

Neurologic manifestations are prevalent and diverse. A classic triad of cognitive dysfunction, ophthalmoplegia, and myoclonus is associated with the disease, but the entire triad is only present in 15%. Oculomasticatory myorhythmia, which entails synchronous contractions of the masticatory muscles with vergence of eye movements, is considered pathognomonic for Whipple disease. Cognitive impairment is subacute to chronic in duration and can advance to a dementia that coexists with substantial behavioral changes. Hypothalamic involvement may also be seen with hypersomnolence, hyperphagia, and autonomic dysfunction. Cerebellar ataxia, seizures, supranuclear ophthalmoplegia, and cranial neuropathies may also occur.

Diagnosis

Diagnosis remains a challenge. In classic Whipple disease, small bowel biopsy with periodic acid–Schiff staining and PCR testing is necessary. Multiple sites should be biopsied because the organism can be both focal and limited in number. If periodic acid–Schiff staining is positive, the diagnosis is probable but requires follow-up with PCR to confirm definite Whipple disease. A positive PCR need not come from the small bowel and can be used from any affected site, including the synovial fluid and CSF.

Treatment and Outcome

Antibiotic treatment starts with 2 weeks of induction therapy with either intravenous ceftriaxone or meropenem. This is followed by 1 year of maintenance antibiotics with either oral sulfamethoxazole-trimethoprim or combination of oral doxycycline and hydroxychloroquine. There are similar efficacies between the oral maintenance regimens, although doxycycline and hydroxychloroquine are often preferred when neurologic involvement is present.

The prognosis for CNS infection is poor, and the fatality rate is 25% within 4 years of onset. Survivors have significant sequelae as the neurologic symptoms are not transient. Even in the absence of neurologic involvement, relapses are common with some patients ultimately placed on life-long antibiotic therapy.

Mycoplasma pneumoniae

Mycoplasma pneumonia is a generally benign respiratory illness, often referred to as *walking pneumonia*, that is caused by the atypical bacterium *Mycoplasma pneumoniae*. Its lack of a cell wall allows it to fuse and enter cells in the lungs, thus evading the host immune response and resisting the effects of antibiotics. Although typically confined to the lungs, extrapulmonary manifestations, including neurologic complications, do occur.

Epidemiology

The disease is ubiquitous worldwide. The estimated incidence is approximately 1 case per 1,000 individuals per year and accounts for up to 40% of community-acquired pneumonias. Children and the elderly are most susceptible, and transmission occurs following inhalation of aerosolized particles obtained from the cough of a close contact. As a result, outbreaks tend to occur in schools, households, military quarters, and nursing homes.

Clinical Manifestations

Pulmonary manifestations are the mainstay of *Mycoplasma* infections and are dependent on age. Children younger than 5 years of age tend to develop upper respiratory infections, persons aged 5 to 20 years develop either bronchitis or pneumonia, and older adults typically develop pneumonia. The classic presentation is a dry cough, fever, and headache that develop several days after exposure. Findings on pulmonary auscultation will be minimal or absent, although chest radiographs will clearly demonstrate pulmonary infiltrates. Extrapulmonary complications do occur and include hemolytic anemia, thrombocytopenic purpura, retinal vasculitis, renal disease, and neurologic involvement.

Neurologic complications are rare but occur in 5% to 7% of hospitalized patients with *M pneumoniae* infection. The most frequent presentation is childhood encephalitis that notably may lack preceding respiratory involvement. Postinfectious complications are more common and thought to be immune-mediated with a predilection for the pediatric population and include myelitis, GBS, and acute disseminated encephalomyelitis.

Diagnosis

In uncomplicated disease, clinical history and chest radiograph are usually sufficient for diagnosis. Serologic testing with enzyme immunoassay comparing acute and convalescent serum samples is the most readily available test. PCR of sputum or nasopharynx samples is a superior test given its higher specificity and speed, but it is often inhibited by cost. Classically, detection of serum cold agglutinins can support the diagnosis early in the disease course, but specificity is limited by its cross-reactivity with other organisms, and enzyme immunoassay and PCR are preferred.

Results of CSF analysis are dependent on the neurologic syndrome. In encephalitis, a lymphocytic pleocytosis, elevated protein concentration, and normal or mildly decreased glucose concentration is present. Albuminocytologic dissociation is seen with GBS. In postinfectious disease syndromes, PCR is often negative, and the diagnosis is confirmed by serology. In myelitis, neuroimaging with MRI demonstrates T2 hyperintensities in the thoracic cord that may be longitudinally extensive.

Treatment and Outcome

Treatment has traditionally been with azithromycin, although macrolide resistance is increasing. Doxycycline is an alternative, and it is often preferred with neurologic involvement given its perceived superior CNS penetration. Corticosteroids are often added to antibiotics in postinfectious neurologic syndromes and additional immunotherapies, such as intravenous immunoglobulin or plasma exchange (PLEX), may be considered.

Clinical recovery often takes several weeks in uncomplicated disease even with appropriate antimicrobial agents. In the absence of antibiotics, recovery may take months. Neurologic sequelae are minimal in GBS or acute disseminated encephalomyelitis and severe with encephalitis. At least one-third of encephalitis patients will have sequelae that include persistent focal neurologic deficits, seizures, and cognitive impairment.

TOXINS

Bacteria can produce toxins that mediate neurologic disease. The most common diseases associated with toxins are diphtheria, botulism, and tetanus (Table 66.4). These disorders are able to cause peripheral nervous system dysfunction by inducing demyelination of peripheral nerves or by preventing release of neurotransmitters at presynaptic terminals.

Diphtheria

Corynebacterium diphtheriae is a gram-positive bacillus that is the causative agent of diphtheria. Humans are the only known host and may be asymptomatic when infected. Transmission occurs either through the lungs (pharyngeal diphtheria) or the skin (cutaneous diphtheria) and is mediated by an exotoxin that induces cell death by interfering with protein synthesis. With neurologic involvement, the toxin induces Schwann cell apoptosis leading to demyelination of peripheral nerves.

Epidemiology

Diphtheria became rare in the United States when widespread vaccination was introduced in the 20th century with less than 10 cases reported since the year 2000. Comparatively, there is approximately 5,000 cases reported worldwide yearly. The majority of these cases occur in India and Madagascar, and other countries in Asia and Africa are known to be endemic areas as well. Cases are usually attributed to lack of immunization or incomplete immunization.

Clinical Manifestations

The most common presentation of pharyngeal diphtheria is pharyngitis with a low-grade fever. Pharyngeal pseudomembranes, a dense gray patch on the posterior pharynx, are classically seen. If the larynx becomes involved, stridor and respiratory arrest can occur. Congestive heart failure from myocarditis and renal failure are other common complications. In contrast, cutaneous diphtheria, which typically involves infection of preexisting skin lesions, often lacks systemic complications.

The likelihood of developing neuropathy is dependent on the severity of the illness. The disease course is biphasic. Lower cranial

TABLE 66.4 Toxins

Disease	Causative Bacterium	Mechanism of Action	Neurologic Features	Diagnosis	Treatment
Diphtheria	*Corynebacterium diphtheriae*	Exotoxin inhibits protein synthesis in Schwann cells leading to demyelination.	Peripheral neuropathy: lower cranial neuropathies with profound bulbar weakness most common (dysarthria, dysphagia, and facial weakness) followed by extraocular muscle weakness and autonomic dysfunction Extremity weakness occurs weeks later with quadriplegia common.	Throat culture of pharyngeal exudates with polymerase chain reaction for toxin detection Electromyography: consistent with demyelinating polyneuropathy	Antibiotics: erythromycin or intramuscular procaine penicillin PLUS Antitoxin
Botulism	*Clostridium botulinum*	Toxin inhibits acetylcholine release at presynaptic nerve terminals. Leads to diminished transmission of peripheral motor and autonomic nerves	Infant botulism: hypotonic infant with weak cry and suck, absent gag reflex, ptosis, mydriatic pupils, ophthalmoplegia, respiratory distress Foodborne botulism: pentad of dry mouth, nausea/vomiting, dysphagia, diplopia, and fixed dilated pupils; also upper extremity and facial weakness, ptosis, and decreased gag reflex	Detection of toxin in serum, stool, or suspected food sources with mouse-based assay or enzyme-linked immunosorbent assay Electromyography: Repetitive stimulation demonstrates facilitation with high-frequency repetitive stimulation.	Infant botulism: human-derived botulism immunoglobulin Foodborne botulism: equine-derived heptavalent botulism antitoxin Wound botulism: same as foodborne botulism with addition of wound debridement and antibiotics
Tetanus	*Clostridium tetani*	Toxin inhibits neurotransmitter release at presynaptic nerve terminals of inhibitory neurons. Leads to hyperactivity of peripheral motor, cranial, and autonomic nerves	Severe muscle spasms starting with involvement of cranial nerve-innervated muscles: facial spasms (sardonicus), lockjaw (trismus), and laryngospasm Spasms later involve axial and extremity muscles (opisthotonos); autonomic dysfunction with labile heart rates and blood pressures	Diagnosis made clinically	Intramuscular antitoxin, benzodiazepines or neuromuscular blockade for spasms, and tetanus toxoid vaccine; antibiotics if wound present

neuropathies occur first with profound bulbar symptoms. Dysarthria and dysphagia are universally seen with most having facial weakness. Weakness of extraocular muscles and autonomic dysfunction are also common. Extremity weakness occurs weeks later, either following resolution of cranial neuropathies or during their recovery, and is severe with almost half becoming quadriplegic at the nadir.

Diagnosis

Diagnosis can be made with throat culture in pharyngeal diphtheria along with PCR to detect if the bacterium is toxigenic. As neuropathy develops following resolution of pharyngeal infection, throat cultures are likely to be negative. In addition, detection of IgG against diphtheria toxin is of little use because this is expected to be present in previously vaccinated individuals. The diagnosis then is based on the history of pharyngitis with a dense gray patch on the posterior pharynx. If CSF analysis is performed, albuminocytologic dissociation is observed in the majority. Nerve conduction studies are particularly helpful because they will be consistent with a demyelinating polyneuropathy.

Treatment and Outcome

Recommendations by the CDC for treatment of pharyngeal diphtheria include antibiotics and antitoxin LEVEL 1. Oral or intravenous erythromycin or intramuscular (IM) procaine penicillin should be given for 14 days. Antitoxin should be given as early as possible to reduce the likelihood of developing neurologic complications. Close contacts should receive antibiotic prophylaxis for 7 to 10 days with oral erythromycin or one dose of IM benzathine penicillin along with a booster dose of diphtheria toxoid vaccine if more than 5 years from last booster.

Approximately 5% to 10% infected with pharyngeal diphtheria will die. This may be higher in those with diphtheria neuropathy, likely due to autonomic dysfunction and cardiovascular compromise. Survivors recover to some extent with 90% reporting mild deficits 1 year later.

Botulism

Botulism is caused by a gram-positive and spore-producing bacillus, *Clostridium botulinum*. Human disease is induced by botulinum toxin with seven known subtypes (A-G). Botulism can be classified clinically into five types: infant botulism, foodborne botulism, wound botulism, adult intestinal colonization botulism, and iatrogenic botulism.

Pathophysiology

Disease is caused by the botulinum toxin, which acts to inhibit acetylcholine release at presynaptic nerve terminals by interfering with proteins involved in neurotransmitter vesicle fusion. These proteins include SNAP-25, which is affected by botulinum toxin types A, C, and E; synaptobrevin, which is affected by types B, D, F, and G; and syntaxin, which is affected by type C. The ultimate result is diminished neural transmission of both peripheral motor and autonomic nerves.

Epidemiology

Botulism is uncommon in the United States with approximately 150 cases per year. Infant botulism is the most common of the five types of botulism, accounting for approximately 70% of cases. Ingestion of honey is considered the main risk factor, although with increased education and awareness, the number of cases has been dramatically reduced. Adult intestinal colonization botulism and iatrogenic botulism make up less than 1% of cases. Foodborne and wound botulism make up about 15% of cases each. Foodborne botulism is typically caused by homemade canning or fermentation because this provides the proper environment for germination of *C botulinum* spores. Prevention is through proper refrigeration and cooking, which inactivates the toxin and spores. Wound botulism can infect any preexisting skin lesion, although it is particularly prevalent in persons who inject black tar heroin.

Clinical Manifestations

Infant botulism manifests as hypotonia with weak cry and suck, diminished or absent gag reflex, and ptosis. Mydriatic pupils, ophthalmoplegia, and respiratory distress are also common with 50% requiring intubation. Recovery can be slow, although mortality is low and most make a full recovery.

Foodborne botulism presents with ophthalmoplegia and prominent bulbar weakness accompanied by gastrointestinal symptoms and is followed by a rapidly progressive descending paralysis. The majority will have three or more features of the classic pentad: dry mouth, nausea/vomiting, dysphagia, diplopia, and fixed dilated pupils. On examination, upper extremity and facial weakness, ptosis, and diminished gag reflex are expected. Wound botulism, adult intestinal colonization botulism, and iatrogenic botulism present similarly to foodborne botulism.

Diagnosis

The CDC, in conjunction with local state authorities, conduct laboratory testing for botulism. Diagnosis is confirmed by detection of botulinum toxin in serum, stool, or suspected food sources. Toxin detection is performed with a mouse-based assay or ELISA, although PCR can also be used to detect *Clostridium*. Electromyography can be useful in diagnosis because it can distinguish botulism from mimickers such as GBS, particularly Miller Fisher syndrome, and myasthenia gravis. Because botulism is a presynaptic neuromuscular junction disorder, it shares electrophysiologic features with Lambert-Eaton myasthenic syndrome. Repetitive stimulation is of particular importance because this will demonstrate incremental response (facilitation) to high-frequency repetitive stimulation, a finding not found in GBS or myasthenia gravis.

Treatment and Outcome

The mainstay of treatment is supportive care, usually in the intensive care unit (ICU) because intubation is frequently required. Infant botulism is treated with human-derived botulism immunoglobulin, which is available through the California Department of Public Health. The remaining botulism types are treated with equine-derived heptavalent botulism antitoxin, which is available through the CDC. In wound botulism, wound debridement and antibiotics are added to antitoxin use.

The mortality rate of infant botulism is 1% with most making a complete recovery even in the absence of antitoxin, although it significantly reduces length of hospitalization and ventilator use. The mortality rate is closer to 5% in foodborne botulism, and sequelae of weakness, fatigue, dry mouth, and dizziness are reported in survivors years later.

Tetanus

Tetanus is caused by *Clostridium tetani*, a gram-positive, spore-producing bacillus. *C tetani* spores are found in the soil and the intestinal tract of humans and other animals. Disease is caused when tetanus spores enter areas of skin breakdown and germinate, producing tetanus toxin (tetanospasmin) in the process.

Pathophysiology

The toxin travels in the blood to peripheral nerve terminals, undergoing retrograde transport in axons to peripheral nerve cell bodies. The toxin then travels across the synapse to presynaptic nerve terminals of inhibitory neurons of the spinal cord and brainstem. There, it cleaves synaptobrevin, a protein necessary for fusion of synaptic vesicles, thus preventing neurotransmitter release and decreasing inhibitory signals. This produces hyperactive peripheral motor, autonomic, and cranial nerves.

Epidemiology

Tetanus is rare in the United States with an average of 30 cases yearly. Approximately 30% of tetanus cases in the United States occur in intravenous drug users and those with diabetes mellitus due to infection of chronic ulcers. Asia and Sub-Saharan Africa have a much higher incidence with India reporting more than 2,000 cases yearly. The increased use of tetanus vaccine has decreased the worldwide incidence by 10-fold since the early 1980s.

Approximately 35% of tetanus cases worldwide occur in neonates, which is most often due to infection of the umbilical stump in infants born to unvaccinated mothers. Infection of the umbilical stump is usually precipitated by use of unhygienic instrumentation. Excluding neonatal and maternal tetanus, men are more likely than women to become infected, presumably due to lower vaccination rates and increased occupational injuries.

Clinical Manifestations

The incubation from injury to onset of symptoms in adult tetanus is 7 to 10 days. The most prominent feature is muscle spasms due to disinhibition of peripheral and cranial motor neurons, beginning 2 to 4 days after onset of symptoms and lasting for approximately 2 weeks. When muscles that are innervated by cranial nerves are affected, features such as sardonicus (facial spasm that produces a smiling appearance), trismus (lockjaw), and laryngospasm are common. Axial and extremity involvement results in rigidity with spasms of the limbs, abdominal, and paraspinal muscles. Opisthotonos, with arching of the back resulting from head, neck, and spine extension, is also common. Autonomic dysfunction can develop by the second week with labile blood pressures, excessive sweating, and tachycardia or bradycardia. ICU care is necessary for several weeks because severe bulbar weakness makes intubation necessary.

Neonatal tetanus is similar to adult tetanus in presentation. Signs present in adults, such as risus sardonicus and opisthotonos, are also commonly present in neonates. Key differences include a more rapid progression and a refusal to feed early in the course. Umbilical sepsis is also found in the majority and, with the combination of spasms, should raise suspicion for the diagnosis.

Diagnosis

Tetanus remains a clinical diagnosis because culture is neither sensitive nor specific. Given that tetanus is rare with protective concentrations of antibody, the diagnosis of tetanus should be reconsidered if serum antibody titers with ELISA are greater than 0.1 IU/mL. Although electromyography is usually unnecessary, certain features can support the diagnosis such as continuous and involuntary spontaneous motor activity due to disinhibition of motor neurons. Other mimickers include hypocalcemia, which can easily be excluded by blood testing and clinically by the presence of perioral and extremity paresthesias. In neonatal tetanus, electroencephalogram may be required to differentiate spasms from seizures.

Treatment and Outcome

Acute management centers on airway management, toxin neutralization, treatment of spasms, and, if necessary, wound treatment. Intubation in an ICU setting is usually required, although early tracheostomy may be considered if endotracheal tube compromise due to laryngeal spasm develops. IM injections of antitoxin, either human tetanus immunoglobulin or equine antitoxin, should be administered to neutralize circulating toxin and prevent further neurologic complications. Spasms can be managed with high doses of benzodiazepines, which are considered first line. Neuromuscular blockade may be necessary if spasms remain uncontrolled. If wounds are present, they should be cleaned thoroughly and debrided with administration of oral or IV metronidazole or penicillin G for 7 to 10 days. Tetanus toxoid vaccine is also given in acute tetanus because it may act as a competitive inhibitor for binding sites in the spinal cord and brainstem.

Mortality rates are highest in neonates and are dependent on access to ICU intervention. Approximately 5% to 10% will die with ICU care versus 60% to 80% without ICU care. Long-term sequelae occur in a quarter of infants with developmental delay, cognitive impairment, and cerebral palsy being frequent. For adults, prevention of tetanus with vaccination remains important. For those with wounds of any type, a dose of tetanus toxoid vaccine should be administered if vaccination status is unknown or if fewer than three doses of vaccine have been administered. For persons with major wounds such as burns, punctures, frostbite, animal bites, or necrotic tissue, tetanus immunoglobulin in addition to tetanus toxoid vaccine should be administered prophylactically.

Chronic Meningitis 67

Prashanth S. Ramachandran, Joseph R. Zunt, Kelly J. Baldwin, and Michael R. Wilson

KEY POINTS

1. The evaluation of a patient with chronic meningitis requires careful history taking regarding immune status, occupational, travel, and contact history. The sensitivity and specificity of the appropriate investigations should be known by the clinicians because each potential pathogen has a test of choice, and the wrong test can lead to incorrect diagnoses.
2. Despite multiple standard investigations, a causative pathogen may not be found, and more agnostic testing such as 16s and 18s polymerase chain reaction or metagenomic next-generation sequencing should be considered to try and arrive at a diagnosis early. Meningeal biopsy should be considered in cases for which serum and cerebrospinal fluid testing do not yield a diagnosis.

INTRODUCTION

Chronic meningitis is commonly defined as inflammation of the meninges, most often accompanied by a pleocytosis of greater than 5 white blood cells per microliter in the cerebrospinal fluid (CSF), that has persisted for at least 1 month without spontaneous resolution. Clinical presentation often includes symptoms of elevated intracranial pressure (ICP)-like headache, nausea, vomiting, or focal neurologic deficits like cranial neuropathies (Table 67.1). The most common etiologies of chronic meningitis fall into three broad categories: infectious, autoimmune, and neoplastic. This chapter focuses on the most common infectious etiologies of chronic meningitis, including fungal, bacterial, and parasitic pathogens. Increasing use of immunosuppressant medications for autoimmune disease and posttransplantation immunosuppression as well as predisposing conditions, such as impaired cellular and humoral immunity, have led to a larger population at risk for infectious causes of chronic meningitis.

GENERAL DIAGNOSTIC APPROACH

The first step to diagnosing a patient with chronic meningitis will always be a careful history to assess for risk factors and exposures to narrow the list of candidate infectious and noninfectious etiologies. Risk factors can be divided into host risk factors and environmental risk factors. With regard to the host, it is critical to assess a patient's immune status because certain pathogens primarily infect the immunocompromised. Careful history taking regarding intravenous (IV) drug use and sexual history are important aspects. Environmental factors mainly focus on potential infectious exposures based on migration or travel as well as sick contacts and exposures to animals and arthropods. Next, a comprehensive physical examination is necessary to assess for evidence of infection, malignancy, or rheumatologic disease systemically as well as a detailed neurologic examination to uncover abnormalities including papilledema (suggestive of raised ICP), cranial nerve palsies, and other focal neurologic signs, which can help direct downstream investigations like neuroimaging and neurophysiologic studies.

Neuroimaging with magnetic resonance imaging (MRI) can help identify the type of meningitis (pachymeningitis vs leptomeningitis) and also whether the meningitis is diffuse or more focal such as in cases of basilar meningitis or ventriculitis. MRI also allows one to assess for other associated abnormalities including the presence of subarachnoid or parenchymal cysts or associated encephalitis or myelitis. All these factors can help provide clues about which potential types of pathogens or noninfectious etiologies to prioritize for more targeted investigation with blood and CSF testing. Blood is useful for cultures, specific fungal testing (eg, cryptococcal antigen), pathogen-specific serologies and noninfectious conditions including a rheumatologic evaluation, evidence for neoplasm, and toxicology studies. From CSF, different patterns of abnormalities in the basic CSF parameters (ie, cell count and differential, protein, and glucose) can be very helpful in directing more specific diagnostic tests as discussed in the following text. It is important to culture CSF for Bacteria, acid fast bacilli, and fungi as well as appropriate pathogen-specific polymerase chain reaction (PCR) tests, serologies, cytology, and antigen testing.

Despite a careful workup, a large proportion of patients with chronic meningitis fail to have an etiology identified. If a diagnosis is not readily made with these initial tests, it is recommended to proactively consider more broad-based testing strategies. These can include assessing levels of galactomannan, 1,3-β-D-glucan (BDG) in CSF, which are elevated in the context of many different types of fungal infections as well as more unbiased, hypothesis-free testing such as 16s and 18s ribosomal RNA (rRNA) PCR for bacteria and fungi, respectively, as well as CSF metagenomic next-generation sequencing (mNGS), which can identify RNA and DNA viruses, fungi, bacteria, and parasites. Ultimately, a meningeal biopsy may be required (Tables 67.2 and 67.3).

FUNGAL MENINGITIS

Fungi exist in two forms, molds and yeasts. Molds are the tubular form, consisting of hyphae that can be branched or contain a single filament. Yeasts are thick-walled, single-celled organisms that live inside cells. Dimorphic yeasts assume tubular forms at lower temperature but become encapsulated at temperatures above 35°C. Either fungal form can infect the nervous system, producing meningitis, vasculitis, abscess, granulomas, or encephalitis.

TABLE 67.1 Neurologic and Systemic Symptoms and Imaging Characteristics of Chronic Infectious Meningitis

Condition	Neurologic Presentation	Systemic Symptoms	Neuroimaging
Cryptococcosis	Headache and fever (75%), nausea and vomiting (50%), altered mental status (50%), visual symptoms, seizures	Pulmonary, multiorgan involvement	Hydrocephalus, cerebral edema, leptomeningeal enhancement, and cryptococcomas
Coccidioidomycosis	Headache (75%); nausea and vomiting (40%); altered mental status (39%-73%); focal neurologic deficits, including ataxia, gait disturbance, diplopia, or facial palsies (33%-80%); and nuchal rigidity (20%)	Pulmonary, lymph nodes, skin	Hydrocephalus, meningeal enhancement, nodular enhancement, basilar meningitis, cerebral infarction
Blastomycosis	Focal neurologic deficits, seizures, and altered mental status Less common: fever, headache, and meningismus	Pulmonary, verrucous or fungating skin lesions, bones, joints, genitourinary system	Single or multiple abscesses, granuloma, meningeal enhancement, epidural extensions, and overlying osteomyelitis
Histoplasmosis	Headache and altered mental status	Acute pulmonary infection with fever, chills, and pulmonary opacities Multiorgan, including bone marrow	Normal, granuloma, meningeal enhancement
Aspergillosis	Solitary mass lesion, cavernous sinus thrombosis, multiple intracranial abscesses, acute or chronic basilar meningitis, vasculitis, or myelitis	Pulmonary, sinusitis, multiorgan involvement	Multiple abscesses, meningeal enhancement, infarction, hemorrhage, sinusitis with extension
Tuberculosis	Headache, vomiting, meningeal signs, focal deficits, vision loss, cranial nerve palsies	Pulmonary, malaise, anorexia, fatigue, weight loss, fever, myalgia	Enhancement of the basilar meninges, thick exudates, obstructive hydrocephalus, miliary pattern, tuberculoma, and periventricular infarcts
Syphilis	Meningitis (headache, photophobia, nausea and vomiting, cranial nerve deficits), general paresis, psychiatric illness, cognitive decline, tabes dorsalis, or vascular disease	Genital ulcers, fever, lymphadenopathy, headache, malaise, myalgia, and a macular or pustular rash of the palms and soles Multiorgan involvement	Leptomeningeal enhancement, white matter disease in the brain and posterior columns, ischemic stroke
Borreliosis	Early: septic lymphocytic meningitis, cranial neuritis, or painful polyradiculitis Late: myelitis, encephalitis, and neurobehavioral changes	Rash, fever, diffuse aches and pains, headaches, malaise, fatigue, carditis	White matter edema with enhancement

Fungi are universal saprophytic organisms found as spores in soil, on the skin of mammals and birds, and in bat or bird guano. They commonly enter the body through inhalation; direct invasion through the skin, mucus membranes, or sinuses; or via penetrating wounds. Fungal infections of the nervous system mainly occur in the presence of immunosuppression as a consequence of AIDS, cancer, hematologic malignancy, hereditary immune defects, organ or stem cell transplantation, or other conditions requiring therapeutic immunosuppression. However, some organisms such as *Coccidioides* and certain *Cryptococcus gatii* species can also affect immunocompetent individuals.

Cryptococcal Meningitis

Epidemiology and Pathobiology

Cryptococcal meningitis is most often caused by the encapsulated yeast *Cryptococcus neoformans*, but other cryptococcal species, such as *Cryptococcus gattii*, are emerging as pathogens that affect immunocompetent individuals. With a worldwide distribution, *C neoformans* is ubiquitous, found primarily in bird droppings, soil, and citrus peel. *C gattii* is more commonly associated with the bark of several tree species. Infection usually occurs through inhalation of the organism, followed by a respiratory infection and dissemination. Cryptococcal meningitis is most common in people with impaired cell-mediated immunity, especially those with human immunodeficiency virus (HIV) infection, hematologic malignancies, solid organ transplant recipients, and patients on chronic corticosteroids or other immunosuppressive therapy. In patients immunocompromised due to HIV infection, *C neoformans* is the most frequent CNS infection, with a prevalence varying from 10% in the United States to as high as 30% in sub-Saharan Africa.

Clinical Features

Cryptococcus neoformans

The clinical manifestations of *C neoformans* infection depends largely on the host immune status. Severity of infection varies from asymptomatic incidental pulmonary nodules to widely disseminated disease. HIV-infected patients with CD4 counts of less than 50 cells/μL are especially vulnerable to disseminated infection and meningitis. Cryptococcal meningitis typically begins insidiously, with 75% of patients developing headache and fever over a 2- to 4-week period. As the infection evolves, 50% of people develop nausea, vomiting, and altered mental status. Visual symptoms and seizures are also common. Over half of immunocompromised patients develop intracranial hypertension; this is even more common in immunocompetent hosts. As increased ICP develops, patients become obtunded, and without intervention, herniation will follow.

TABLE 67.2 Cerebrospinal Fluid Characteristics and Serum Diagnostics for Chronic Infectious Meningitis

Condition	Microscopic Appearance	LP Opening Pressure	CSF WBC	CSF Differential	CSF Glucose	CSF Protein	CSF Diagnostics	Serum Diagnostics
Cryptococcosis	Encapsulated fungi; yeast-like cells with budding daughter cells; capsule visualized by India ink (halo effect)	High	High or normal	Mononuclear	Low	High	Fungal smear, fungal culture, India ink stain, CrAg LFA	Blood culture
Coccidioidomycosis	Yeast form endosporulating spherules; branched septate hyphae with alternating arthroconidia	Normal	High	Early PMN, lymphocytic, eosinophilic (70%)	Low	High	Fungal culture, microscopy, complement fixation antibody assay, PCR	Microscopy from BAL fluid, or other body fluid, or a positive culture from any location
Blastomycosis	Mycelium at room temperature; yeast phase at 37°C; conidia, yeast cells with multinucleate broad budding	High	High	Early PMN, lymphocytic	Low	High	Fungal culture, biopsy of involved tissue with microscopy	Direct visualization of the organism via microscopy
Histoplasmosis	Hyphae large macroconidia and smaller infectious microconidia. At temperatures <35°C, yeast form; hyphal elements possible	Normal	High	Mononuclear	Low	High	Fungal smear and culture, antigen titers	Fungal culture from involved organ, antigen titers
Aspergillosis	Septate hyphae branched at 45° angles with conidiophores. Hyphae develop terminal buds forming small conidia.	Normal	High	Early neutrophil, lymphocytic	Low	High	Fungal culture, biopsy of affected tissue with microscopy, PCR	Galactomannan and β-D-glucan; microscopy, culture, or PCR from BAL or affected tissue
Tuberculosis	Intracellular aerobic gram-positive acid-fast pleomorphic bacillus	High	High or normal	Mixed pleocytosis	Low	High	AFB smear and culture, PCR; GeneXpert, MODS	QuantiFERON, PPD, BAL for AFB smear and culture; GeneXpert Ultra
Syphilis	Spirochetal bacterium	Normal	High or normal	Lymphocytic	Normal	High or normal	Darkfield microscopy, VDRL, PCR	RPR, VDRL (FTA-ABS), and *Treponema pallidum* particle agglutination tests (MHA-TP)
Borreliosis	Spirochetal bacterium	Normal	High	Lymphocytic	Normal	High or normal	Darkfield microscopy, IgG and IgM antibody index, PCR	Two-tier testing (ELISA and IgM/IgG immunoblot)

Abbreviations: AFB, acid-fast bacillus; BAL, bronchoalveolar lavage; CrAg, cryptococcal capsular polysaccharide antigen; CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; FTA-ABS, fluorescent treponemal antibody absorption; IgG, immunoglobulin G; IgM, immunoglobulin M; LFA, lateral flow assay; LP, lumbar puncture; MHA-TP, Microhemagglutination assay – *Treponema pallidum*; MODS, microscopic observation drug susceptibility; PCR, polymerase chain reaction; PMN, polymorphonuclear; PPD, purified protein derivative; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory; WBC, white blood cell.

Cryptococcus gattii

This is a rare pathogen, with disease previously confined to tropical and subtropical climates, particularly the highly endemic regions of Australia and Papua New Guinea. In 2004, an outbreak of *C gattii* infections was documented in the United States Pacific Northwest states of Oregon and Washington. A large retrospective review of the Pacific Northwest *C gattii* infections revealed important clinical differences between *C gattii* infections in the Pacific Northwest and historically endemic areas. Although *C gattii* in historically endemic areas has been reported to infect primarily immunocompetent persons, causing meningoencephalitis, *C gattii* infections in Oregon and Washington state occurred most frequently in immunocompetent persons and presented most often as respiratory illness. Time from symptom onset to diagnosis of *C gattii* infection was significantly longer among patients with pulmonary infections (50 d) than those with either CNS (24 d)

TABLE 67.3 Treatment of Chronic Infectious Meningitis

Condition	Treatment	Alternatives and Other Considerations
Cryptococcosis	AmB 0.7-1 mg/kg/d IV plus flucytosine 100 mg/kg/d × 14 d then fluconazole 400 mg orally daily × 8 wk then fluconazole 200 mg daily lifelong	Repeat LP to keep opening pressures in normal range; CSF shunting when needed
Coccidioidomycosis	Induction therapy with oral fluconazole 400-1,200 mg/d, followed by 800-1,200 mg/d indefinitely	Itraconazole 400-600 mg/d or amphotericin B 0.5-0.7 mg/kg/d. Intrathecal amphotericin B in addition to an azole; shunting for hydrocephalus when needed
Blastomycosis	Liposomal amphotericin B, 5 mg/kg/d for 4-6 wk, followed by an oral azole. Possible options for azole therapy include fluconazole (800 mg/d), itraconazole (200 mg 2 or 3 times per day), or voriconazole (200-400 mg twice per day) for at least 12 mo and until resolution of CSF abnormalities.	Surgical drainage of any epidural abscess
Histoplasmosis	Liposomal amphotericin B (5.0 mg/kg daily for a total of 175 mg/kg given over 4-6 wk). Fluconazole (800 mg/d) should be continued for 9-12 mo.	Chronic fluconazole maintenance therapy (800 mg/d) in relapsing patients. Intrathecal amphotericin B.
Aspergillosis	Voriconazole 6 mg/kg IV twice a day on day 1 followed by 4 mg/kg IV twice daily, followed by maintenance therapy of voriconazole 200 mg every 12 h.	Voriconazole plus caspofungin for invasive disease
Tuberculosis	Intensive four-drug regimen × 2 mo then continuation two-drug regimen × 10 mo based on resistance patterns	Choice of treatment should be directed by resistance patterns. Steroids should be considered for meningitis.
Syphilis	Aqueous penicillin G 18-24 million U/d administered as 3-4 million units IV every 4 h or as continuous infusion for 10-14 d	Procaine penicillin 2.4 million units IM daily with probenecid 500 mg orally 4 times daily for 10-14 d
Borreliosis	Ceftriaxone 2 g IV daily for 14 d Doxycycline 100 mg twice daily for 10-21 d	IV cefotaxime or IV penicillin G; oral doxycycline

Abbreviations: AmB, amphotericin B; CSF, cerebrospinal fluid; IM, intramuscular IV, intravenous; LP, lumbar puncture.

or bloodstream infections (27 d). There were no differences in immune status between patients with bloodstream infections and either pulmonary or CNS infections.

Diagnosis

The diagnosis of cryptococcal meningitis should be considered in patients presenting subacutely with headache and fever, especially in the setting of HIV infection or immunosuppression. Computed tomography (CT) and MRI are nonspecific for the diagnosis of cryptococcal meningitis but may reveal hydrocephalus, cerebral edema, leptomeningeal enhancement, or cryptococcomas. Classic MRI findings for fungal meningitis are shown in Figure 67.1. Lumbar puncture, the diagnostic procedure of choice, demonstrates an increased opening pressure, a mild mononuclear pleocytosis, increased protein, and low glucose concentrations. Patients with severe immunosuppression may lack this typical CSF profile. The cryptococcal capsular polysaccharide antigen (CrAg) assay is both sensitive and specific for detecting *C neoformans* in CSF samples and can be quantitated for prognostication. The CrAg titer is not reliable for determining response to therapy. Although a positive CrAg assay in serum cannot confirm the diagnosis of cryptococcal meningitis, a negative CrAg assay virtually excludes the diagnosis, at least in HIV-infected patients. Because the CrAg lateral flow assay has nearly 100% sensitivity and specificity on CSF samples, it is considered the optimal point-of-care diagnostic assay for cryptococcal meningitis. In areas where CrAg is not available, direct CSF examination with India ink preparation is often used. Fungal culture for the organism is 90% sensitive and can also be useful for speciation, although it typically requires days for culture to grow. *C neoformans* cultured from CSF, blood, or other sites produces white mucoid (depending on the capsule thickness) colonies, usually within 48 to 72 hours, on most bacterial and

FIGURE 67.1 Axial brain magnetic resonance imaging. **A:** T2 fluid-attenuated inversion recovery with leptomeningeal hyperintensity in the posterior frontal lobe. **B:** Diffusion-weighted imaging demonstrating pus in the posterior horn of the lateral ventricle. **C,D:** T1 postcontrast with avid leptomeningeal enhancement.

fungal media. Although *C neoformans* grows at 37°C, a temperature of 30°C to 35°C is optimal. HIV-1 infected patients with a $CD4^+$ count lower than 100 cells/mm^3 in regions where the burden of cryptococcal antigenemia is high should be screened with a serum CrAg and treated with oral fluconazole to prevent development of cryptococcal meningitis. Patients who are serum CrAg-positive should be screened for neurologic symptoms and a lumbar puncture should be performed. Treating these high-risk patients presumptively with combination antifungal therapy for cryptococcal meningitis can be considered.

Treatment Update

A combination of antifungal medication and aggressive management of hydrocephalus is integral to the successful treatment of patients with cryptococcal meningitis. Antifungal therapy is divided into induction therapy, consolidation and maintenance. Amphotericin B (AmB) plus flucytosine, as compared with AmB alone, is associated with improved survival of patients with cryptococcal meningitis for induction therapy LEVEL 1.[1] When AmB cannot be administered due to drug access or safety, the oral combination of fluconazole plus flucytosine is an effective alternative LEVEL 1.[2] Fluconazole is then used for consolidation and maintenance therapy. Adjunctive dexamethasone use among patients with HIV with cryptococcal meningitis resulted in poorer outcomes LEVEL 1.[3] In patients with untreated HIV-1, antiretroviral therapy initiation should be delayed to minimize the risk of cryptococcal meningitis immune reconstitution inflammatory syndrome. Delaying antiretroviral therapy initiation for more than 4 weeks of cryptococcal meningitis induction therapy is associated with improved survival LEVEL 1.[4]

Elevated ICP can be managed through a variety of treatments. Patients should initially undergo daily lumbar punctures to reduce opening pressure until normal opening pressure is consistently maintained; some patients may require multiple daily lumbar punctures. For patients requiring frequent lumbar punctures, placement of a lumbar drain or ventriculostomy can provide a temporary means for controlling ICP. Ventriculoperitoneal shunt can be considered for patients with persistently elevated ICP. A recent retrospective study of elevated ICP in patients with cryptococcal meningitis determined that aggressive management of ICP during the initial 5 days of illness was associated with lower mortality than initial antifungal management alone.

Although guidelines for treatment of cryptococcal disease are based primarily on data from *C neoformans* infections in HIV and solid organ transplant patients, these guidelines are intended to apply to patients with *C neoformans* or *C gattii* infections. A limited number of *C gattii*–specific recommendations were included for the first time in the 2010 Infectious Diseases Society of America guidelines and are based on data from *C gattii* infections in historically endemic areas. These recommendations pertain mainly to patients with cryptococcomas, which previous data have suggested are more common in patients infected with *C gattii* than *C neoformans*, and include consideration of surgery for patients with large cryptococcomas, increased radiologic and follow-up evaluations for those with cryptococcomas or hydrocephalus, and possible use of AmB/flucytosine in patients with large and/or multiple pulmonary cryptococcomas.

Outcomes

Poor prognostic factors include low CSF glucose concentration, high CSF cryptococcal antigen titer (>1:1,024), high CSF lactate level, altered level of consciousness, hydrocephalus, and elevated ICP.

Coccidioidomycosis

Epidemiology and Pathobiology

Coccidioides immitis is a fungus endemic to the Southwestern United States, Northern Mexico, and areas of South America. The mycelial phase of *Coccidioides* species is able to withstand extreme desert climates and after rainfalls will multiply to form arthroconidia. Infection in humans occurs when aerosolized arthroconidia are inhaled. Once inhaled, *C immitis* usually results in a self-limited respiratory infection, commonly known as *valley fever*. In susceptible populations, a pulmonary infection can progress to severe disseminated disease. Dissemination is more likely to occur in patients of African or Asian descent, pregnant women, and people who are immunocompromised, especially due to HIV infection or long-term immunosuppressive therapy.

Clinical Features

Similar to tuberculosis (TB), chronic meningitis due to *C immitis* classically involves the basilar meninges. The most common symptom is headache, which is present in over 75% of patients. Other presenting signs and symptoms are related to elevated ICP and include nausea and vomiting (40%); altered mental status (39%-73%); focal neurologic deficits, including ataxia, gait disturbance, diplopia, or facial palsies (33%-80%); and nuchal rigidity (20%).

In patients with HIV infection, coccidioidomycosis can resemble *Pneumocystis jiroveci* pneumonia, producing a unique reticulonodular diffuse infiltrative pulmonary disease and constitutional symptoms of dyspnea, fever, and night sweats. Coccidioidomycosis frequently disseminates in patients with HIV infection, with common sites of dissemination including the meninges, lymph nodes, and skin. Although patients who are HIV-positive can present with unique symptoms, most HIV-infected patients present with symptoms similar to those seen in immunocompetent patients. Hydrocephalus, cerebral infarction, and vasculitis are potential complications of *C immitis* meningitis. Communicating hydrocephalus is a well-known complication of basilar meningitis, secondary to obstruction of arachnoid villi blocking reabsorption of CSF and may develop during the initial or later stages of the infection. Hydrocephalus develops in about 20% to 50% of patients with *C immitis* meningitis and is associated with a 12-fold increased risk of mortality. Cerebral infarction, as well as venous and dural thrombosis, has been reported during the initial and later stages of infection. Perivascular inflammation is typically associated with infarction of the basal ganglia, thalamus, and cerebral white matter.

Diagnosis

Coccidioidomycosis can be diagnosed using serologic testing, histopathology, or culture of tissue or fluid from the infected site. Identification of *C immitis* spherules in tissue, sputum, and bronchoalveolar lavage (BAL) fluid, or a positive culture from any location in the body, is diagnostic of coccidioidal infection. Definitive diagnosis of *C immitis* meningitis requires identification or culture of the organism from the brain or CSF. Unfortunately, CSF culture is often negative and presumptive diagnosis is typically made through a combination of CSF and serologic testing. CSF is typically abnormal, with a lymphocytic pleocytosis with early neutrophil predominance and low glucose concentration. Of note, this pathogen may cause a CSF eosinophilia in up to 70% of patients with meningitis, a finding that is relatively uncommon with other fungal pathogens.

Detection of antibodies to *C immitis* in the CSF using the complement fixation antibody assay is the most sensitive test for confirming meningeal infection. Repeated CSF sampling is sometimes required to confirm the diagnosis because antibody test results can be negative early during the course of infection (71%-94% sensitive). Enzyme immunoassay for immunoglobulin M and immunoglobulin G (IgG) and latex agglutination tests are less sensitive in CSF samples. Although PCR assays have been used to detect *C immitis* infection, they are not routinely available.

Treatment

Oral fluconazole is recommended for the treatment of *C immitis* meningitis. Practice guidelines recommend oral fluconazole 400 to 1,200 mg/d. Higher rates of treatment failure have been noted at 400 mg/d, and most experts recommend dosing at the higher end of the spectrum (800-1,200 mg) Itraconazole, administered in dosages of 400 to 800 mg/d, has been reported to be comparably effective. Intrathecal AmB in addition to an azole-based therapy can be used as a rescue therapy when azole therapy is ineffective.

Hydrocephalus nearly always requires a neurosurgical shunt for decompression. Patients who do not respond to fluconazole or itraconazole are candidates for intrathecal AmB therapy with or without continuation of azole treatment. The most common life-threatening complication of coccidioidal meningitis is CNS vasculitis leading to cerebral ischemia, infarction, and hemorrhage. Some physicians endorse the use of concomitant high-dose, IV, short-term corticosteroids, but larger randomized studies are lacking.

Outcomes

Approximately 66% to 80% of patients treated with oral azoles alone achieved initial clinical improvement or remission of meningitis. However, up to 75% of patients relapse; therefore, lifelong prophylaxis with fluconazole 400 mg/d is recommended. Without treatment, the frequency of relapse is high and outcome poor.

Blastomycosis and Histoplasmosis

Epidemiology

Blastomyces dermatitidis and *Histoplasma capsulatum* are dimorphic fungi endemic to the Mississippi and Ohio River valleys. Although isolated cases of infection have been reported outside this geographic area, most patients reside within these areas. *Histoplasma* and *Blastomyces* species are ubiquitous environmental organisms, existing in the mycelial phase and then converting to the yeast phase at body temperature. Both organisms produce a large spectrum of disease, ranging from subclinical infection to disseminated disease.

Pathobiology

B dermatitidis, a thick-walled yeast with broad-based budding daughter cells, is endemic to the Great Lakes and Mississippi and Ohio River valleys. Like histoplasmosis, infection with blastomycosis is acquired via inhalation of spores into the lung and can manifest as pulmonary or extrapulmonary disease. Chest radiographs commonly demonstrate nodular or lobar infiltrates with cavitations. If the organism evades nonspecific host defense mechanisms in the lungs, it will convert into the yeast phase and multiply. The organism then spreads hematogenously to other organs. Cutaneous involvement is seen in 60% of patients with blastomycosis, manifesting as verrucous or fungating lesions with irregular borders. Other sites less frequently involved include bones, joints, genitourinary system, and the CNS.

H capsulatum, like *B dermatitidis*, is primarily found in the Mississippi and Ohio River valleys, and infection is acquired via inhalation. Histoplasmosis may produce an acute pulmonary infection with fever, chills, and lung opacities on chest imaging. Patients with impaired cellular immunity, such as HIV-infected individuals, typically present with chronic pulmonary symptoms with progression to severe disseminated disease. Infection disseminates hematogenously to distant sites, such as the liver, spleen, and CNS. Bone marrow involvement is common and often manifests as thrombocytopenia, anemia, or leukopenia.

Clinical Features

CNS infection with blastomycosis occurs in less than 10% of people with disseminated disease and manifests as solitary or multiple abscesses and acute or chronic meningitis. Unlike other fungal CNS infections, blastomycosis is more likely to present with focal neurologic deficits, seizures, and altered mental status, whereas symptoms of fever, headache, and meningismus are less common. Although intracranial infection results most frequently from hematogenous seeding of the brain parenchyma from the lungs, epidural extension from overlying vertebral or skull osteomyelitis has been described.

Most patients with pulmonary histoplasmosis are asymptomatic and have resolution of the infection without therapy. It is common for individuals in the Mississippi and Ohio River valleys to have asymptomatic pulmonary nodules. Dissemination occurs during both primary infection and reactivation of latent infection. CNS involvement occurs in less than 20% of patients with disseminated infection and most frequently affects patients with severely impaired cellular immunity, such as people who are HIV-infected. Presenting symptoms typically include headache and altered mental status; although less common, patients may also present with focal neurologic deficits, seizures, ischemic stroke, and mass lesions.

Diagnosis

Direct visualization of blastomycosis via microscopy is the only method of rapid diagnosis but has variable sensitivity. Lumbar puncture typically reveals elevated opening pressure, and CSF is notable for elevated protein concentration, low glucose concentration, and a pleocytosis with neutrophilic predominance early in the disease course followed by a lymphocytic predominance. The gold standard for diagnosis remains CSF culture, which is positive in 70% of patients with blastomycosis. Growth of *B dermatitidis* on culture media can occur within 5 to 10 days but may take 2 to 4 weeks for definitive identification of the organism. More invasive procedures, such as brain biopsy and ventricular sampling of CSF, are more likely to provide sufficient material for definitive diagnosis and are often needed for diagnosing intracranial disease. The use of CSF and serum antigen titers and antibodies are useful, although as with histoplasmosis, significant cross-reactivity occurs with other dimorphic fungi.

In histoplasmosis meningitis, CSF frequently demonstrates a mononuclear pleocytosis, increased protein concentration, and decreased glucose concentration. CSF culture is not sensitive for diagnosing histoplasmosis. The use of CSF and serum antigen titers and antibodies are useful, although as with blastomycosis, significant cross-reactivity occurs with other dimorphic fungi.

Because meningitis is typically the result of disseminated infection, testing for the organism in the blood or bone marrow should also be considered.

Treatment

AmB should be given for blastomycosis infection as a lipid formulation at a dosage of 5 mg/kg/d for 4 to 6 weeks, followed by an oral azole. Possible options for azole therapy include fluconazole (800 mg/d), itraconazole (200 mg 2 to 3 times per day), or voriconazole (200-400 mg twice per day) for at least 12 months and until resolution of CSF abnormalities. Patients with immunodeficiency due to HIV or immunosuppressive therapy have high rates of relapse and should be maintained on long-term secondary prophylaxis with fluconazole indefinitely. For selected patients with neurologic dysfunction caused by focal CNS blastomycosis, surgery may be beneficial. Surgical drainage of an epidural abscess may be necessary for reducing morbidity and mortality from this disorder.

Treatment of CNS histoplasmosis is challenging. Despite treatment with AmB, mortality ranges from 20% to 40% of patients with meningitis, and up to half of responders relapse after therapy is discontinued. The optimal treatment for *H capsulatum* meningitis is liposomal AmB (5.0 mg/kg daily for a total of 175 mg/kg given over 4-6 wk). To reduce the risk of relapse, fluconazole (800 mg/d) should be continued for 9 to 12 months after completion of AmB. Chronic fluconazole maintenance therapy (800 mg/d) should be considered for patients who relapse after completing a full course of therapy. Itraconazole, although more active against *H capsulatum* in animal models, does not cross the blood-brain barrier in adequate amounts to treat CNS infection. Intrathecal administration of amphotericin directly into the ventricles, cisterna magna, or lumbar arachnoid space should be reserved for severe infections that do not respond to conventional therapy.

Aspergillosis

Epidemiology and Pathobiology

Aspergillus species are ubiquitous soil inhabitants that grow and survive on organic debris. This fungus sporulates abundantly, releasing conidia into the atmosphere in large quantities. The conidia are small in diameter, making it possible to reach smaller areas of the lung, including the alveoli. Although humans inhale several hundred conidia per day, inhalation of organisms rarely results in disease because the conidia are efficiently eliminated by host immune mechanisms. Alveolar macrophages and neutrophils constitute the first line of host defense against aerosolized conidia.

Historically, disease was limited to individuals with repetitive exposure to pathogens, producing a mild condition known as *farmer's lung*. *Aspergillus* species can also produce lung aspergillomas, characterized as an overgrowth of fungus in preexisting cavitary lung lesions. More recently, the incidence and severity of *Aspergillus* species infections has increased due to a growing number of people living with immunosuppression, leading to the disease known as *invasive aspergillosis*. Populations significantly at risk for invasive aspergillosis include patients undergoing treatment for hematologic malignancies, recipients of allogeneic hematopoietic stem cell transplant and solid organ transplant, people who are HIV infected, and individuals with chronic granulomatous disease.

Clinical Features

Cerebral aspergillosis occurs in approximately 10% to 20% of patients with invasive disease and results from hematogenous dissemination of the organism or via direct extension from rhinosinusitis. CNS infection can present as a solitary mass lesion, cavernous sinus thrombosis, multiple intracranial abscesses, acute or chronic basilar meningitis, vasculitis, or myelitis. Pathologically, cerebral aspergillosis has a propensity for vascular invasion, infarction, hemorrhage, and aneurysm formation; as a result, the clinical presentation may mimic cerebral vasculitis, ischemic or hemorrhagic infarction, or subarachnoid hemorrhage. In patients with suspected cerebral aspergillosis, it is important to examine the lungs and sinuses for evidence of infection and potential sites for obtaining biopsy or culture material.

Diagnosis

Diagnosis of aspergillosis in immunocompromised patients remains difficult. As with many invasive fungal CNS infections, diagnosis is often achieved through examination of the primary entry site of infection. Thus, in patients with suspected CNS aspergillosis, it is important to examine the lungs and sinuses for evidence of infection and potential sites for obtaining biopsy or culture material. MRI of the brain typically reveals a manifestation of infection, such as cerebral infarction, hemorrhagic lesions, solid-enhancing aspergillomas, or ring-enhancing abscesses. Dural enhancement is usually seen in lesions adjacent to infected paranasal sinuses and indicates direct extension of disease.

Several serum laboratory markers can aid in the diagnosis of invasive aspergillosis. Enzyme-linked immunosorbent assay (ELISA) testing for the fungal cell wall constituents galactomannan and BDG should be considered. The CSF galactomannan assay using latex agglutination or ELISA may be a useful adjunct to serum testing; however, data is limited to small sample sizes with variable performance and reliability (sensitivity of 70%-90%). BDG is the major cell wall component of most fungal species, and BDG antigen testing is used as a broad test for detection of fungal pathogens. *Cryptococcus* species do not contain high levels of BDG in their cell walls and therefore are not detected. BDG antigen testing is helpful for detecting invasive aspergillosis and candidiasis. Several PCR assays can detect *Aspergillus* species in blood and BAL fluid samples; a recent study to detect *Aspergillus* species in fresh tissue and BAL fluid reported a sensitivity and specificity of 86% and 100%, respectively. Experience with PCR to detect *Aspergillus* species in CSF samples is limited.

Treatment

Unfortunately, cerebral aspergillosis, especially in an immunocompromised patient, is difficult to treat and has a high mortality rate. The use of voriconazole, a newer antifungal agent, has reduced the mortality of an infection that was previously associated with almost universal mortality. Clinical trials have demonstrated that voriconazole is more effective than AmB as initial therapy for invasive aspergillosis and is associated with significantly improved survival (71% vs 58%, respectively). In vitro studies evaluating combination therapy with voriconazole and caspofungin for *Aspergillus* species have provided promising results in patients with invasive aspergillosis.

TUBERCULOSIS

Epidemiology and Pathobiology

Mycobacterium tuberculosis is an intracellular aerobic gram-positive acid-fast pleomorphic bacillus that can cause chronic meningitis. Transmission occurs primarily by inhalation of airborne droplet nuclei into the lungs. *M tuberculosis* multiplies in alveolar macrophages, and within weeks, the bacilli can hematogenously disseminate to extrapulmonary sites, including the meninges and adjacent brain parenchyma. Tuberculous meningitis is an aggressive form of extrapulmonary disease that is more common in patients infected with HIV.

Clinical Features

Meningitis is typically preceded by nonspecific symptoms of malaise, anorexia, fatigue, weight loss, fever, myalgia, and headache. In immunocompetent patients, headache, vomiting, meningeal signs, focal deficits, vision loss, cranial nerve palsies, and raised ICP are characteristic clinical features. Cerebral vessels may be affected by adjacent meningeal inflammation, producing vasospasm, constriction, and eventually thrombosis with cerebral infarction. As the disease progresses, the patient will become comatose from elevated ICP and obstructive hydrocephalus.

Diagnosis

Despite its many limitations, tuberculin skin testing remains in widespread use. The Centers for Disease Control and Prevention (CDC), the American Thoracic Society, and the Infectious Diseases Society of America's guidelines recommend that one should not obtain a tuberculin skin test unless treatment would be offered in the event of a positive test result. Negative results from the purified protein derivative test do not rule out TB; if the 5-tuberculin skin test result is negative and suspicion for TB is high, the test can be repeated with the 250-tuberculin test. Note that this test is often nonreactive in persons with tuberculous meningitis.

Diagnosing tuberculous meningitis can be difficult and typically involves a combination of neuroimaging, serologic studies, and CSF analysis. Meningitis in the setting of concomitant pulmonary TB is highly suggestive of tuberculous meningitis. Both CT and MRI of the brain are valuable for diagnosing TB meningitis and evaluating for complications. The hallmark pathologic feature of tuberculous meningitis is the presence of a thick exudate most prominent in the basilar meninges. Thus, characteristic abnormalities include enhancement of the basilar meninges, thick exudates, obstructive hydrocephalus, and periventricular infarcts (Fig. 67.2). Chest CT is sensitive for detecting pulmonary abnormalities in patients with tuberculous meningitis.

Characteristic CSF abnormalities include a mononuclear pleocytosis, low glucose concentration, and elevated protein concentration. CSF pleocytosis can be lower in HIV-infected patients. Of note, 16% of patients with confirmed cryptococcal meningitis, 5% with TB, and 4% with bacterial meningitis will have normal CSF cell counts and biochemistry. Although CSF acid-fast bacillus smear and culture are crucial for making a diagnosis of tuberculous meningitis, there is a wide range of reported sensitivities for acid-fast bacillus smear; sensitivities can reach as high as 52% when large volume CSF samples (>6 mL) are evaluated by microscopy for at least 30 minutes. Conventional CSF culture for *M tuberculosis* on Lowenstein-Jensen medium is positive in approximately 45% to 90% of cases but usually takes several weeks for a positive result. The microscopic observation drug susceptibility assay was recently endorsed for rapid screening of multidrug-resistant TB. This technology uses an inverted light microscope to examine liquid culture for growth of the characteristic "cord"-like structures of TB. This can be completed in 7 to 10 days, compared to conventional solid culture that takes several weeks. Other assays that may prove more sensitive include detection of intracellular bacteria by a modified Ziehl-Neelsen stain and early secretory antigenic target-6 in CSF leukocytes. Detection of *M tuberculosis* DNA in CSF by PCR assay

FIGURE 67.2 Axial brain magnetic resonance imaging. **A,B:** T1 postcontrast with multiple ring-enhancing lesions seen in miliary tuberculosis. **C,D:** T1 postcontrast with large L frontal tuberculoma. **E,F:** T1 postcontrast demonstrating avid basilar meningitis with leptomeningeal enhancement.

is a useful ancillary diagnostic test, with nearly 100% specificity, but sensitivity varies between 30% and 50%, thus limiting its usefulness. The GeneXpert Ultra is currently the most sensitive test available for the detection of TB meningitis. It relies on fully automated, nested DNA-PCR technique for detection of TB and rifampicin resistance. Compared to a microbiologic composite, it has a sensitivity of 95%. However, against a uniform clinical definition of tuberculous meningitis used for research purposes, it only had a sensitivity of 70%.

Treatment

Empiric treatment should be initiated when tuberculous meningitis is initially suspected because the organism grows slowly, speciation and resistance patterns can take weeks, and earlier treatment is associated with better outcomes. First-line antituberculous medications include rifampicin, isoniazid, pyrazinamide, and ethambutol LEVEL 2.[5] Multidrug-resistant and extremely drug-resistant TB pose a serious and growing problem, and treatment should be individualized based on sensitivity testing. Adjunctive corticosteroids significantly reduce death and disabling residual neurologic deficits LEVEL 1[6] and are currently used regardless of HIV status, although evidence for added benefit for HIV-infected patients is inconclusive, and studies are ongoing.

NEUROSYPHILIS

Neurosyphilis has played an important role in the evolution of modern neurology. Paretic neurosyphilis was the first psychiatric disorder for which a specific cerebral pathology and treatment was reported. Erb described spinal syphilis tabes dorsalis in 1892. Quincke introduced lumbar puncture, and CSF examination was used to diagnose infection, even in asymptomatic people. *Treponema pallidum* was identified in the brain by Noguchi and Moore in 1913. The first effective treatment came in 1918 when Wagner-Jaurregg gave fever therapy for paresis. He was the first psychiatrist to win the Nobel Prize. Then came arsenical chemotherapy, the first planned use of a drug that would attack the organism without harming host tissues; this was Ehrlich's concept of "the magic bullet." Safer and more effective therapy came in 1945 with the introduction of penicillin, which has been in use since and has revolutionized treatment of the disease. Following the introduction of penicillin in the 1940s and 1950s, the incidence of neurosyphilis declined for two main reasons: (1) Fewer people spread the disease because those affected were being identified and treated, and (2) many neurosyphilis infections were prevented because penicillin was being used to treat gonorrhea and other infections. For instance, the frequency of neurosyphilis as a cause of first admission to a psychiatric hospital plummeted from 5.9 cases per 100,000 population in 1942 to 0.1 cases per 100,000 in 1965. New cases became so rare that many hospitals discarded routine testing to detect syphilis.

During the next few decades, some investigators detected a shift in clinical patterns, but this finding was debated. The population at highest incidence was young homosexual men. Finally, in 1981, the AIDS epidemic occurred. The incidence of primary and secondary syphilis rose from 13.7 cases per 100,000 in 1981 to 18.4 cases per 100,000 in 1989, an increase of 34%. In the ensuing years, the incidence of syphilis declined. In 1997, fewer than 8,000 cases of early syphilis were reported in the United States, the lowest rate in 38 years and a sixfold decline from 1990. Unfortunately, since 2000, there has been an unexpected increase in new cases of primary and secondary syphilis in the United States. Trends in Western Europe, Brazil, and Canada were similar, presumably because of a resurgence of unsafe sexual practices. In addition to the alarming increase in the incidence of syphilis in industrialized countries, syphilis, like HIV, is an enormous health problem in developing countries. For instance, syphilis seropositivity among pregnant women in sub-Saharan Africa may be higher than 10%. Even before the HIV era, there had been a shift in clinical manifestations because of the widespread use of antibiotics. Previously common parenchymal forms became rare, whereas the incidence of meningeal (including meningitis, radiculitis, and cranial neuritis) and vascular syndromes have increased.

Epidemiology and Pathobiology

Syphilis is caused by the thin, motile corkscrew bacterium *T pallidum*. This organism cannot be routinely cultured in the laboratory and is difficult to visualize using traditional light microscopy. Transmission is primarily via sexual contact with an infected individual or by vertical transmission from mother to fetus. Without treatment, the disease will inevitably progress through a series of clinical stages. In general, syphilis can be classified as early or late infection. Early infection encompasses primary, secondary, and early latent syphilis. Late infection refers to tertiary syphilis.

Clinical Features

After sexual exposure to the organism, an asymptomatic incubation period of approximately 3 weeks occurs, followed by the development of a painless genital ulceration or chancre. If left untreated, the chancre will resolve in 3 to 5 weeks, and the disease will progress to secondary syphilis. Secondary syphilis is a syndrome of fever, lymphadenopathy, headache, malaise, myalgia, and a macular or pustular rash of the palms and soles. During this stage, involvement of other organ systems produces clinical symptoms, including mucosal lesions, renal failure, hepatitis, and neurologic symptoms. The signs and symptoms of secondary syphilis typically resolve in 4 to 10 weeks, and the patient is deemed latently infected. About one-third of patients with untreated latent syphilis will progress to develop late or tertiary syphilis, which can affect any organ in the body, particularly the nervous system, manifesting with a variety of symptoms.

T pallidum spreads hematogenously to the CNS early in the course of disease, and clinical signs and symptoms are not limited to any particular disease stage. Patterns of meningitis or vascular disease may be more common earlier in disease, whereas late disease presents as parenchymal or spinal cord pathologies. Although neurosyphilis can produce a wide variety of manifestations, including general paresis, psychiatric illness, cognitive decline, tabes dorsalis, or vascular disease, this section limits the discussion to syphilitic meningitis.

Syphilitic meningitis typically presents in the secondary stage of syphilis within 2 years of acquiring infection. Although meningitis is less common than other forms of neurosyphilis, abnormal CSF with a mononuclear pleocytosis and elevated protein concentration occurs in up to 25% of patients. The most common presenting symptoms include headache, photophobia, nausea and vomiting, meningismus, and cranial nerve deficits. Although any cranial nerve can be affected, cranial nerves VII and VIII are most commonly affected.

Diagnosis

The diagnosis of neurosyphilis is typically made through a combination of history, physical examination, and results of serologic and CSF analyses. Two forms of serologic testing are used in the diagnosis of syphilis: nontreponemal testing, such as the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) assays, and treponemal testing, such as fluorescent treponemal antibody absorption and *T pallidum* particle agglutination (TPPA) tests. Nontreponemal assays detect IgG and immunoglobulin M antibodies to a cardiolipin-lecithin cholesterol antigen and can normalize with treatment or even in chronically infected patients who have not been treated. Treponemal assays measure treponemal antibodies and remain positive for life, even with appropriate treatment. The order of treponemal or nontreponemal testing is dependent on local institutional practices. Generally, treponemal testing is performed first (TPPA) to screen for current or past infection followed by a nontreponemal assay (RPR) to assess for a possible treatment response. The 2018 CDC neurosyphilis diagnostic criteria require a positive serum RPR, a positive serum TPPA, and CSF abnormalities. In syphilitic meningitis, CSF typically has a mononuclear-predominant pleocytosis, elevated protein concentration (>45 mg/dL), and normal or decreased glucose concentration. Although CSF immunologic tests, such as VDRL, are very specific and are usually abnormal in syphilitic meningitis (70% sensitivity), a negative result does not rule out neurosyphilis. More recently, PCR assays have been developed to detect *T pallidum* in the CSF, but 50% of patients with syphilitic involvement of the CNS have a negative PCR. Other new techniques include using CSF fluorescent treponemal antibody and percentage of CSF B cells when CSF-VDRL is negative to aid in establishing the diagnosis of neurosyphilis.

Treatment

Penicillin is the first-line therapy for neurosyphilis. The CDC recommends 18 to 24 million units of aqueous penicillin G per day administered as 3 to 4 million units IV every 4 hours or as a continuous infusion for 10 to 14 days. An alternative is procaine penicillin 2.4 million units intramuscular daily with probenecid 500 mg orally 4 times daily for 10 to 14 days

LYME DISEASE

Epidemiology

North American Lyme borreliosis, or Lyme disease, is the most common tick-borne infection in the United States. The CDC reports that 300,000 cases of Lyme disease are diagnosed in the United States each year, with 96% of cases concentrated in 13 states (Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Virginia, and Wisconsin). In humans, the signs and symptoms of Lyme borreliosis most frequently appear in spring, summer, and early autumn, coinciding with the activity of nymphs and with the increasing recreational use of tick habitats by the public.

Pathobiology

Lyme disease is caused by *Borrelia burgdorferi*, which is transmitted by specific *Ixodes* species ticks. In Europe, at least five species of Lyme *Borrelia* (*Borrelia afzelii*, *Borrelia garinii*, *B burgdorferi*, *Borrelia spielmanii*, and *Borrelia bavariensis*) can cause the disease, leading to a wider variety of possible clinical manifestations in Europe than in North America. Transmission of the organism occurs through injection of tick saliva during feeding. A feeding period of more than 36 hours is usually required for transmission of *B burgdorferi* by *Ixodes scapularis* or *Ixodes pacificus*. In North America, the only species of Lyme *Borrelia* known to cause human disease are *B burgdorferi*, *Borrelia miyamotoi*, and *Borrelia mayonii*.

Clinical Features

Spirochetes initially proliferate at the site of the tick bite. When sufficiently numerous, they slowly migrate centrifugally from the site of inoculation, typically for up to 30 days after the bite. The associated skin lesion associated with this proliferating, spreading infection is known as *erythema migrans*. Erythema migrans consists of an area of erythroderma that enlarges over days to weeks, often reaching several inches in diameter. Depending on the location on the body, the rash may be round or elliptical. Central pallor may be present.

Early disseminated disease is usually characterized by a multifocal rash, with each new focus representing a nidus of spirochetes that spread hematogenously from the initial site. The bacterial dissemination is accompanied by the usual host inflammatory reaction to bacteremia: fever, diffuse aches and pains, headaches, malaise, and fatigue. Up to 5% of infected individuals develop heart block, known as *Lyme carditis*, sometimes requiring a temporary pacemaker. Early dissemination affects the nervous system in 10% to 15% of patients, primarily in the first few months after the initial infection, during what is often termed *acute disseminated infection*. Most commonly, patients present with an aseptic lymphocytic meningitis, cranial neuritis, or painful polyradiculitis. First described in Europe, Garin-Bujadoux-Bannwarth syndrome is now considered to include all or part of a classic triad: lymphocytic meningitis, cranial neuritis, and polyradiculitis. Cranial and peripheral nerve involvement can occur anywhere along the course of affected nerves, not preferentially in the subarachnoid space. Approximately three-fourths of patients with Lyme-associated cranial neuropathies present with a facial nerve palsy. Early studies suggested this could be bilateral in up to one quarter of cases.

Late Lyme disease can manifest as arthritis or the skin disorder known as *acrodermatitis chronica atrophicans*, a tissue paper thinning of the skin. Neurologic manifestations of late Lyme disease include myelitis, encephalitis, and neurobehavioral changes. Much attention has focused on patients who have persistent fatigue and cognitive difficulty after receiving treatment for Lyme disease with regimens that should be highly effective even for severe infections, a disorder often referred to as *post–Lyme syndrome*. This topic is controversial and is beyond the scope of this chapter.

Diagnosis

Typical erythema migrans is usually sufficiently distinctive to allow a clinical diagnosis in the absence of a supporting laboratory test. Serologic assays for antibodies to Lyme *Borrelia* are positive infrequently at this stage and thus should be obtained only in atypical cases and then in conjunction with convalescent phase serologic testing 2 to 6 weeks after obtaining the acute sample. Treatment at this stage will prevent progression to neurologic Lyme disease.

The majority of patients with early Lyme disease are seropositive on serum two-tier testing (ELISA and IgG immunoblot). Those who are seronegative at presentation will convert in 2 weeks after acute phase. CSF testing for intrathecal antibody production and lumbar puncture showing lymphocytic meningitis are useful to confirm diagnosis. CSF PCR is insensitive for the diagnosis of neurologic Lyme disease and should not be routinely used. Late neurologic Lyme disease requires a positive serum two-tier (ELISA and IgG immunoblot) seropositivity and evidence of intrathecal antibody production. CSF examination generally supports an active infection with a lymphocytic meningitis, elevated protein concentration, and normal glucose concentration.

Treatment

For adult patients with early Lyme disease and the acute neurologic presentation of meningitis or radiculopathy, ceftriaxone 2 g IV daily for 14 days is recommended. Parenteral therapy with cefotaxime LEVEL 1[7,8] or penicillin G LEVEL 1[9,10] may be acceptable alternatives. Oral doxycycline has good oral absorption and CNS penetration and may also be an alternative LEVEL 1.[11] Late neurologic Lyme disease may present as encephalomyelitis, peripheral neuropathy, or encephalopathy. These patients should be treated with ceftriaxone 2 g IV once daily for 2 to 4 weeks. Cefotaxime or penicillin G may be acceptable alternatives. Retreatment is not indicated for persistent or recurrent symptoms.

HYPOTHESIS-FREE INVESTIGATIONS

On many occasions, despite high clinical suspicion for an infectious cause of chronic meningitis, no pathogen is detected via conventional investigations. In addition to the many pathogen-specific serologic, antigen, and PCR-based tests described earlier, more broad-based infectious disease diagnostics are being increasingly used, especially in difficult-to-diagnose cases. These included 16s and 18s rRNA PCR assays to detect bacteria and fungi, respectively, as well as mNGS of CSF. The latter is now a clinically validated test for detecting infections in patients with meningitis, myelitis, and/or encephalitis.

The 16s rRNA gene is a highly conserved region in bacteria, whereas the 18s and 28s rRNA genes are highly conserved in fungi. PCR amplification of these genes allows identification of a variety of bacterial and fungal species. In culture-proven cases of meningitis, 16s rRNA PCR was 94% sensitive and specific and was positive in 30% of culture-negative cases. The main reason for discordance was pretreatment with antibiotics before lumbar puncture, leading to diminished culture results.

mNGS allows for the most unbiased approach to diagnosis by amplifying and sequencing all nucleic acid present in a CSF sample with random primers. After extensive bioinformatics processing of the resulting sequences to filter out low quality, redundant, and human sequences, the origin of the nonhuman sequences is determined by searching the remaining sequences in large, public databases to determine whether there might be a pathogen present. Recent papers have demonstrated the use of mNGS in the sphere of chronic meningitis and encephalitis with favorable results. mNGS was able to detect several pathogens causing subacute or chronic meningitis that had not been considered by the treating team as well as aid with management decisions. However, mNGS was more insensitive for the detection of infections that primarily rely on antibody testing as the mainstay of diagnosis, such as *T pallidum* and West Nile virus.

Parasitic Infections 68

Gustavo C. Román

KEY POINTS

1. Neurologic parasitic infections are no longer confined to the tropics.
2. Malaria is the commonest parasitic infection in the world.
3. Due to its elevated mortality, cerebral malaria is a medical emergency.
4. Sleeping sickness (Africa) and Chagas disease (South America) are human trypanosomiasis.
5. Amebic meningitis may occur after swimming in fresh water.
6. Seizures are the main manifestation of neurocysticercosis.
7. Larva migrans is acquired by eating raw meats.
8. Raccoons are the reservoir of North American larva migrans.
9. Bilharziasis often presents with lumbosacral myelopathy.

INTRODUCTION

Parasitic infections are a tremendous public health burden in tropical and subtropical regions of the world. Parasitic tropical diseases of the nervous system can be found also in temperate regions due to the exponential increase in international travel, tourism, and migration. One important factor is the disregard of tourists and business travelers for the prophylactic measures recommended before traveling to parts of the world where potential exposure to endemic parasitic diseases may occur. When neurologists elicit a travel history preceding the onset of the disease, a high index of suspicion should lead to a differential diagnosis of the most common parasitic neurologic diseases in order to diagnose and treat these exotic conditions.

Parasitic Neurologic Diseases

Table 68.1 lists the most common types of parasitic infections of the human nervous system. Parasitic diseases are divided into *protozoan infections* caused by unicellular organisms (malaria, trypanosomiasis, amebiasis) and *metazoan infections* caused by worms (helminths), mainly cestodes or tapeworms (cysticercosis), nematodes or round worms (larva migrans, baylisascariasis, gnathostomiasis, strongyloidiasis), and trematodes or flukes (paragonimiasis). Not included in this chapter are neurologic diseases transmitted by ectoparasites, such as ticks and other arthropods, including Lyme disease (a spirochetal infection caused by *Borrelia burgdorferi*) (see Chapter 67); other forms of borreliosis presenting as relapsing fevers transmitted to humans by lice or ticks (see Chapter 67); and gram-negative bacterial infections, such as the Rickettsial typhus group (caused by *Rickettsia prowazekii* and *Rickettsia typhi*, transmitted respectively by the body louse *Pediculus humanus* and the rat flea *Xenopsylla cheopis*) as well as the spotted fevers transmitted by ticks and caused by *Rickettsia rickettsii* (see Chapter 66). *Toxoplasma gondii* infection is discussed in the context of human immunodeficiency virus infection (see Chapter 70).

CEREBRAL MALARIA

Introduction

Malaria is the most important human protozoan infection worldwide. The rapid development of multidrug resistance *Plasmodium falciparum* malaria in Cambodia and neighboring countries in Southeast Asia increases the mortality and threatens malaria eradication efforts. Resistance to chloroquine and antifolates has been present in Africa and tropical South America for a long time, and there is evidence of early emerging resistance to artemisinin derivatives.

Epidemiology

According to the World Health Organization, in 2018, an estimated 206 million malaria cases occurred worldwide with 405,000 deaths, mainly young children in sub-Saharan Africa. In 2011, the number of malaria cases reported in the United States was the largest since 1971, representing a 48% increase from 2008. Most malaria infections in the United States occurred among travelers to regions with active malaria transmission.

Pathobiology

Cerebral malaria is an acute encephalitis caused by *P falciparum*, the most virulent of the four *Plasmodium* species that infect humans, when a female *Anopheles* mosquito inoculates the protozoan parasites through the skin. Parasites are carried to the liver where they mature and multiply to enter the red cells in the bloodstream.

Diagnosis

Clinical Features

Malaria presents with typical bouts of intermittent fever with chills, rigors, and anemia. Pregnant women are at increased risk for malaria. Cerebral malaria may be heralded by headache, vomiting, and a clinical picture of encephalopathy developing over days in a febrile patient, accompanied by confusion, decreased responsiveness, and somnolence rapidly progressing to stupor and coma. Psychomotor agitation and psychiatric manifestations may precede cerebral malaria. Focal findings are uncommon,

TABLE 68.1 Parasitic Infections of the Nervous System

Name	Agent	Reservoir	Transmission
Metazoan Infections			
Neurocysticercosis	*Taenia solium*	Pigs, humans	Human *Taenia* carriers
Gnathostomiasis	*Gnathostoma spinigerum*	Fish, poultry, dogs, cats	Undercooked fish, poultry
Hydatid cysts	*Echinococcus* species	Dogs, foxes, sheep, cows	Dogs' feces
Larva migrans	*Toxocara canis, Toxocara cati, Ascaris* species	Dogs, cats	Dogs' and cats' feces
Baylisascariasis	*Baylisascaris procyonis*	Raccoon (*Procyon lotor*)	Raccoons' feces
Paragonimiasis	*Paragonimus westermani*	Fresh water crustaceans, snails	Eating uncooked crustaceans
Schistosomiasis/ bilharziasis	*Schistosoma* species	Fresh water snails	Skin penetration by larval forms (cercariae) in infected water
Sparganosis	*Spirometra mansoni*	Reptiles, amphibians	Eating uncooked frogs or snakes
Strongyloidiasis	*Strongyloides stercoralis*	Human	Infected soil contact
Trichinosis	*Trichinella spiralis*	Pigs	Eating undercooked pork
Protozoan Infections			
African trypanosomiasis Sleeping sickness	*Trypanosoma brucei*	Ungulates	Tsetse flies (*Glossina*)
American trypanosomiasis Chagas disease	*Trypanosoma cruzi*	Opossum, dogs	Triatomine bugs
Amebiasis	*Entamoeba histolytica*	Human	Ingestion of food contaminated with feces
Primary amebic meningoencephalitis	*Naegleria* species	Warm fresh water ponds	Nasal route while swimming
Granulomatous amebic encephalitis	*Acanthamoeba* species	Fresh and brackish water	Nasal route while swimming
Cerebral malaria	*Plasmodium falciparum*	Human	*Anopheles* mosquitoes
Toxoplasmosis	*Toxoplasma gondii*	Cat	Cats' feces in contaminated soil or vegetables

except when stroke occurs concurrently. In children, tonic-clonic seizures occur, followed by postictal unresponsiveness.

In adults, cerebral malaria may occur in the setting of severe malaria presenting with acute respiratory distress; pulmonary edema; acute renal failure and hemoglobinuria ("blackwater fever"); jaundice and liver failure; severe anemia; thrombocytopenia; disseminated intravascular coagulation; and bleeding complications, including intracranial hemorrhages. Severe hypoglycemia must be assumed to be present in children with cerebral malaria and should be treated promptly and aggressively.

Retinal hemorrhages and exudates are usually seen on funduscopic examination and reflect the cerebral small-vessel vasculopathy. Meningeal signs do not occur, and cerebrospinal fluid (CSF) is normal; however, spinal tap is mandatory to exclude other causes of encephalopathy. Brain imaging may show evidence of brain swelling and herniation or small hemorrhages.

Diagnostic Methods

Malaria should be considered a potential medical emergency in the United States in a febrile patient with the clinical features mentioned above and with recent history of travel to a tropical region. Rapid diagnosis and treatment improves the prognosis and minimizes the risk of infecting indigenous mosquito populations. Confirmation of malaria requires laboratory diagnosis by an experienced pathologist demonstrating the presence of the *Plasmodium* parasite in the red cells in a Wright- or Giemsa-stained thick or thin blood smear.

A positive BinaxNOW rapid diagnostic test for malaria detects specific malaria antigens and confirms the diagnosis but does not eliminate the need for the blood stain because the type of *Plasmodium* parasite must by confirmed by microscopy. The indirect fluorescent antibody serologic test for malaria becomes positive during convalescence and is not useful in acute malaria. The Centers for Disease Control and Prevention provides diagnostic support for suspected cases of malaria as well as artesunate for treatment of severe cases.

Management

The drugs of choice for treatment of cerebral malaria are the derivatives of artemisinin, such as artesunate, artemether, or arteether. Quinine is an equivalent alternative for cerebral malaria. Development of drug resistance to artemisinin derivatives has occurred in South East Asia and combination therapy for *P falciparum* malaria with other antimalarial drug is recommended. Cerebral malaria is a critical condition and requires intensive care treatment; complications such as hypoglycemia, respiratory distress syndrome, and acute renal and liver failure must be promptly recognized and treated. Severe anemia or bleeding diathesis may require blood transfusions. Steroids are not recommended in cerebral malaria. Despite treatment, the mortality is over 25%, but survivors usually recover without sequelae; however, residual hemiplegia, extrapyramidal symptoms, blindness, deafness, psychiatric symptoms, and epilepsy may occur.

There is intensive research on the immune mechanisms of cerebral malaria leading to vascular occlusion by parasitized erythrocytes, vasoconstriction, and alterations of the blood-brain barrier with decreased cerebral blood flow, edema, demyelination, ischemia, hypoxia, acidosis, and death. Potential therapies based on nitric oxide bioavailability, high levels of endothelin-1, and angiopoietin dysfunction appear promising.

Malaria prevention relies on avoiding exposure to mosquitoes using repellents and insecticide-treated bed nets and prophylactic use of antimalarial drugs prior to, during, and after travel to endemic malaria regions. The *P falciparum* malaria vaccine (RTS,S Mosquirix, GlaxoSmithKline Biologicals S.A.) has been approved by World Health Organization for pilot use in children in three African countries.

TRYPANOSOMIASIS

Two human infections with protozoa of the genus *Trypanosoma* have neurologic importance: African trypanosomiasis (sleeping sickness) and American trypanosomiasis (Chagas disease); both are transmitted by infected arthropods, the tsetse fly (*Glossina* species) in Africa, and triatomine (reduviid) vectors (Fig. 68.1) in South America. The use of organophosphate insecticidal paint (Inesfly 5A IGR) as well as radiation-sterilized male tsetse flies appears promising for vector control.

African Trypanosomiasis

This fatal encephalitis is caused by infection with *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, endemic respectively to East and West Africa. Tsetse fly infests one-third of Africa's landmass representing a problem of appalling magnitude. African trypanosomiasis or *sleeping sickness* is a chronic encephalitis, with diencephalic involvement resulting in disruption of the circadian sleep-wake cycle manifested by excessive daytime sleepiness, sleep attacks similar to those of narcolepsy, and nocturnal insomnia. There are also psychiatric manifestations, seizures, coma, and finally death. The CSF shows lymphocytic pleocytosis and moderate increase in protein concentration and intrathecal production of immunoglobulin M. African trypanosomes can be identified by fine needle aspirate of enlarged cervical lymph nodes as well as in blood and CSF. Oral fexinidazole and the parenteral combination of nifurtimox and eflornithine appear to be promising treatments.

American Trypanosomiasis

Human infection with *Trypanosoma cruzi* (Chagas disease) affects an estimated 10 million people in Latin America causing about 50,000 annual deaths. Presence of infected asymptomatic blood donors in the United States led blood banks to perform routine trypanosome screening with radioimmunoprecipitation.

Acute infection following the bite of triatomine bugs (see Fig. 68.1A) causes subcutaneous swelling typically located in the orbital region (Romaña sign) (see Fig. 68.1B), cervical lymph node enlargement, and acute myocarditis or encephalitis. A striking feature of Chagas disease is the selective neuronal destruction with denervation of the myenteric plexus of the intestine causing megaesophagus and megacolon and denervation of the conduction system of the heart leading to a chronic dilated cardiomyopathy. The dilated heart becomes an important cause of embolic stroke. At autopsy, one-third of patients with chronic Chagas disease have left ventricular thrombi.

T cruzi can be demonstrated in blood or CSF or by serologic testing. Treatment of acute disease or reactivations includes nifurtimox, benznidazole, or itraconazole. There is no effective therapy for chronic Chagas disease. Secondary prevention of stroke with long-term anticoagulation is recommended.

AMEBIC MENINGOENCEPHALITIS

Primary amebic meningoencephalitis is due to infection with the free-living ameba *Naegleria fowleri*. Infection is acquired by swimming in warm bodies of natural or man-made fresh water. The organisms penetrate the cribriform plate and reach the brain causing acute meningoencephalitis and brain abscess.

FIGURE 68.1 A: Triatomine vectors of Chagas disease. *Triatoma dimidiata capitata* **(left)** and *Rhodnius prolixus* **(right). B:** Romaña's sign in a child with acute infection by *Trypanosoma cruzi* following triatomine bite causing subcutaneous swelling in the orbital region with cervical lymph node enlargement. (From Toro G, Román G, Navarro de Román LI, eds. *Neurología Tropical: Aspectos Neuropatológicos de la Medicina Tropical*. Bogotá, Colombia: Editorial Printer Colombiana, Ltda; 1983.)

The clinical presentation is typical of purulent meningitis. The organisms are seldom isolated. Treatment with intravenous and intrathecal amphotericin B, intravenous and intrathecal miconazole, and oral rifampin should be started based on clinical suspicion in patients with meningitis and history of swimming in warm fresh waters.

A chronic granulomatous form of amebic meningoencephalitis often accompanied by cutaneous infection and keratitis is caused by infection with the opportunistic free-living amoebae *Balamuthia mandrillaris* and by several species of *Acanthamoeba* affecting immunosuppressed patients, transplant recipients, or malnourished individuals. Treatment is often unsuccessful.

NEUROCYSTICERCOSIS

Introduction

Neurocysticercosis is the human infection with larval forms (cysticerci) of the pig tapeworm *Taenia solium*. This is the most common cause of epilepsy in the world. Most cases observed in the United States occur in migrants from endemic countries, mainly Mexico and Central and South America. Autochthonous cases also occur from contact with asymptomatic carriers of *T solium*.

Epidemiology

Neurocysticercosis is the most common neurologic infection caused by helminthes (cestodes) in humans (Fig. 68.2). Contrary to common belief, consumption of poorly cooked pork infected with *T solium* cysticerci does not cause neurocysticercosis but results in intestinal tapeworm infection or human taeniasis. Neurocysticercosis occurs from human-to-human transmission of fertilized *T solium* eggs from a human carrier of intestinal *Taenia*. Humans become intermediate hosts in the life cycle of *T solium* by ingesting *Taenia* eggs due to fecal contamination of water or food. Failure of intestinal *Taenia* carriers to wash their hands after defecation is the most common source of infection.

Pathobiology

Ingested eggs hatch in the intestine, enter the bloodstream, and are carried into the host tissues including heart, muscles, and the brain and spinal cord where cysticerci develop into cystic forms called *Cysticercus racemosus* (Latin *racemus*, bunch of grapes). Neurocysticercosis can be prevented with handwashing, clean water, environmental sanitation, and proper pig farming.

Cysticerci are found in the brain parenchyma, the subarachnoid spaces, the ventricular system, the eye, the spinal cord, and intrathecal nerve roots as well as in the heart, the muscles, and subcutaneous tissues. Although many cysticerci fail to elicit a foreign body reaction, inflammation around each cysticercus eventually develops, accompanied by edema, reactive gliosis, and formation of dense exudates in the subarachnoid space composed of collagen, lymphocytes, multinucleated giant cells, eosinophils, and hyalinized parasitic membranes found in parenchymal lesions, but also causing eosinophilic meningitis, ventriculitis, and radiculitis. Stroke may result from involvement of the blood vessels by the inflammation. Even calcified lesions may develop perilesional edema associated with seizure activity.

Diagnosis

Neurocysticercosis is the most common cause of epilepsy in tropical areas of Latin America, Africa, and Asia. It results in 50,000 deaths per year and is a frequent cause of chronic neurologic disorders due to irreversible brain or spinal cord damage. Neurocysticercosis is becoming increasingly prevalent in industrialized countries because of travel and migration. In the United States, 1,494 patients with neurocysticercosis were reported between 1980 and 2004, making it the most common imported disease of the nervous system. According to the Centers for Disease Control and Prevention, each year, an estimated 1,000 new patients are hospitalized in the United States with neurocysticercosis.

Clinical Features

Cysticercosis is a pleomorphic disease capable of producing epilepsy, stroke with focal neurologic deficits, intracranial hypertension, and reversible dementia. Diagnostic criteria have been clearly established. Reported cases in the United States presented with seizures (66%), hydrocephalus (16%), and headaches (15%) due to parenchymal neurocysticercosis brain lesions (91%); the remainder had ventricular cysts (6%), subarachnoid cysts (2%), and spinal cord lesions (0.2%). Calcified neurocysticercosis has been associated with increased risk of cognitive decline.

Diagnostic Methods

The diagnosis of neurocysticercosis is based on clinical findings, a history of travel to endemic regions or potential exposure to *Taenia* carriers, and immunologic tests. The possibility that a patient harbors an intestinal *Taenia* should be explored with repeated examinations of stools for ova and parasites. On neuroimaging, parenchymal neurocysticercosis shows single or multiple cysts in the parenchyma, with the typical "hole-in-donut" appearance with presence of the radiodense scolex of the parasite. In subarachnoid neurocysticercosis, there is abnormal enhancement of the leptomeninges, hydrocephalus, and cystic lesions located at the Sylvian fissure or basal cisterns. Multiple calcified lesions ("starry sky") on computed tomography indicate spontaneous resolution. The CSF usually shows lymphocytic pleocytosis, presence of eosinophils, increased protein (up to 2,000 mg/dL), and normal glucose. Serum immunoblot and CSF enzyme-linked immunosorbent assay are useful confirmatory tests.

Management

The recommended treatment for patients with one to two viable subarachnoid or parenchymal cysts is albendazole for 8 to 15 days; for patients with more than two viable parenchymal cysts, albendazole (15 mg/kg/d) combined with praziquantel (50 mg/kg/d) is recommended usually in combination with dexamethasone to avoid the risk of stroke or brain edema LEVEL 2.[1] Dexamethasone administration should begin prior to the start of albendazole therapy and should be prolonged for several days. Isolated intraventricular cysts in the fourth ventricle are best treated with endoscopic surgery. Shunt placement must be considered before the start of albendazole in patients with hydrocephalus.

FIGURE 68.2 *Taenia solium* life cycle. Cysticercosis is an infection of both humans and pigs with the larval stages of the parasitic cestode, *Taenia solium*. This infection is caused by ingestion of eggs shed in the feces of a human tapeworm carrier ❶. These eggs are immediately infectious and do not require a developmental period outside the host. Pigs and humans become infected by ingesting eggs or gravid proglottids ❷, ❼. Humans are usually exposed to eggs by ingestion of food/water contaminated with feces containing these eggs or proglottids or by person-to-person spread. Tapeworm carriers can also infect themselves through fecal-oral transmission (e.g. caused by poor hand hygiene). Once eggs or proglottids are ingested, oncospheres hatch in the intestine ❸, ❽ invade the intestinal wall, enter the bloodstream, and migrate to multiple tissues and organs where they mature into cysticerci over 60–70 days ❹, ❾. Some cysticerci will migrate to the central nervous system, causing serious sequellae (neurocysticercosis). This differs from taeniasis, which is an intestinal infection with the adult tapeworm. Humans acquire intestinal infections with *T. solium* after eating undercooked pork containing cysticerci ❺. Cysts evaginate and attach to the small intestine by their scolices. Adult tapeworms develop to maturity and may reside in the small intestine for years ❻. (Reprinted from https://www.cdc.gov/parasites/cysticercosis/biology.html.)

LARVA MIGRANS AND EOSINOPHILIC MENINGITIS

Introduction

Infection of the nervous system by nematodes or roundworms occurs when humans become hosts to the parasite and the moving worms migrate producing the clinical syndrome called *larva migrans* usually accompanied by eosinophilic meningitis.

Epidemiology

The most common form of larva migrans of the nervous system in North America is caused by highly motile *Ascaris* of the North American raccoon *Baylisascaris procyonis*, usually acquired by children playing in sand boxes contaminated with raccoon stools. In other parts of the world, the severity of the infection depends mainly on the size and vitality of the parasite, ranging from the severe meningoencephalitis or myelitis caused by the tracts of the spike-covered worm *Gnathostoma spinigerum* in Thailand to the relatively benign eosinophilic meningitis caused in Southeast Asia by *Angiostrongylus cantonensis*, the rat lungworm.

Pathobiology

A history of travel is usually elicited because humans become hosts to the parasite by ingestion of contaminated Japanese-style raw fish, such as sushi and sashimi, and consumption of natural and exotic foods, such as raw mollusks, shrimp, freshwater crustaceans, snails, snakes, frogs, or insufficiently cooked chicken or duck contaminated with the infective larvae of the parasite. Once ingested, the highly motile larvae cross the intestinal wall and migrate to subcutaneous tissues causing cutaneous larva migrans, continuing to visceral larva migrans with involvement of internal organs, skeletal muscles, the eye, and the nervous system. Table 68.2 summarizes the main geographic forms of the larva migrans syndromes and eosinophilic meningitis.

Diagnosis

These conditions usually present with eosinophilic pleocytosis in the CSF demonstrated with the use of the Giemsa or Wright stain showing greater than 10 eosinophils per mL or more than 10% of the total CSF leukocyte count. Eosinophils are effectors of the adaptive immune response (helper T cell type 2) directed against destruction of metazoan multicellular parasites.

Clinical Features

Neurologic forms of presentation include the relatively benign eosinophilic meningitis of angiostrongyliasis to the more severe cases with encephalitis, transverse myelitis, seizures, meningitis, subarachnoid hemorrhage, and focal neurologic deficits associated with parenchymal brain hemorrhages that occur with larger parasites causing gnathostomiasis and baylisascariasis.

Diagnostic Methods

A CSF examination may range from the normal appearance and mild eosinophilic meningitis of angiostrongyliasis to the usually bloody and xanthochromic CSF of gnathostomiasis and baylisascariasis, typically showing severe eosinophilic pleocytosis (up to 3,000 cells/mm^3), mild increase in protein concentration, and normal glucose concentration. Blood eosinophilia is usually present. Neuroimaging shows the tracts of the parasites as long or multiple parenchymal brain hemorrhages or evidence of multiple foci of myelitis. Diagnosis is confirmed by identification of the larvae in CSF or tissue samples.

Management

The recommended treatment of eosinophilic meningomyelitis is a combination of anthelmintics and intravenous corticosteroids, such as albendazole with intravenous dexamethasone.

Outcome

Baylisascariasis and gnathostomiasis may be fatal when undiagnosed and untreated. Deficits may result from spinal cord injuries or brain hemorrhages. Angiostrongyliasis usually causes a benign eosinophilic meningitis.

SCHISTOSOMIASIS (BILHARZIA)

Introduction

Human schistosomiasis is a parasitic disease caused by trematode flukes of the genus *Schistosoma*. Some *Schistosoma* species cause chronic liver damage with portal hypertension, whereas

TABLE 68.2 Nematode (Round Worm) Infections of the Nervous System Causing Larva Migrans Syndrome and Eosinophilic Meningitis

Name	Agent	Geographic Location	Clinical Presentation
Angiostrongyliasis Eosinophilic meningitis	*Angiostrongylus cantonensis* *Angiostrongylus costaricensis*	China, Southeast Asia, Taiwan, Thailand, Vietnam, Australia, South Pacific islands Costa Rica, Central America	Eosinophilic aseptic meningitis
Gnathostomiasis	*Gnathostoma spinigerum*	Southeast Asia	Meningoencephalitis, myelitis, eosinophilic meningitis, cutaneous and visceral larva migrans
Baylisascariasis	*Baylisascaris procyonis*	North America	Meningoencephalitis, myelitis, eosinophilic meningitis, eye involvement, cutaneous larva migrans
Toxocariasis Larva migrans	*Toxocara canis, Toxocara cati* *Ascaris* species	Worldwide	Eosinophilic meningitis, eye involvement, myelitis, encephalitis, cutaneous larva migrans

TABLE 68.3 Clinical Syndromes and Geographic Distribution of Schistosomiasis

Clinical Syndromes	Agent	Geographic Location
Parasitic myelitis (conus medullaris)	*Schistosoma mansoni*	Africa, Middle East, Caribbean, Brazil, Venezuela, Suriname
Intestinal schistosomiasis	*Schistosoma japonicum*	China, Indonesia, Philippines
Liver fibrosis with portal hypertension		
Meningoencephalitis	*Schistosoma haematobium*	Africa, Middle East
Urogenital schistosomiasis	*Schistosoma intercalatum*	West Africa
Squamous cell carcinoma of the bladder	*Schistosoma guineensis*	East Africa
	Schistosoma mekongi	Mekong river basin

others produce bladder and urogenital lesions in chronic carriers. Involvement of the spinal cord and meningoencephalitis are the main neurologic complications.

Epidemiology

Some 230 million people worldwide are infected with *Schistosoma* species. The geographic distribution of different agents of schistosomiasis is summarized in Table 68.3. Parasitic adult worms remain in the venous circulation for years, evading the immune system and excreting over 100,000 fertile eggs daily. Immune responses of the host to the parasites' eggs explain the pathology of schistosomiasis.

Pathobiology

Neurologic involvement occurs during the early postinfective stage when *Schistosoma japonicum* eggs reach the brain causing meningoencephalitis; infection with *Schistosoma mansoni* and *Schistosoma haematobium* produce preferential involvement of the spinal cord (myelitis and myeloradiculitis), particularly of the conus medullaris, cauda equina, or the spinal cord. *Schistosoma* ectopic eggs reach the central nervous system through retrograde venous flow into the Batson venous plexus.

Diagnosis

Clinical Manifestations

The parasitic myelopathy of schistosomiasis can be manifested as an acute painful flaccid paraplegia with areflexia, sphincter dysfunction, urinary incontinence, impotence, and sensory disturbances; acute transverse myelitis, spastic paraplegia, painful lumbosacral radiculopathy with backache, and cauda equina syndrome also occur.

Diagnostic Methods

The diagnosis must be suspected on the basis of a clinical presentation of acute painful lumbosacral myelopathy or conus medullaris syndrome with imaging findings suggestive of bilharziasis in a patient with history of travel or exposure to *Schistosoma* cercariae after swimming in fresh water. The diagnosis is confirmed by demonstration of *Schistosoma* antibodies in serum and/or CSF and presence of *Schistosoma* eggs in biopsy of rectal mucosa or in stools and urine.

Management and Outcome

The myelitis of schistosomiasis usually responds to treatment with the schistosomicidal drug praziquantel in combination with steroids; other schistosomicidal drugs are oxamniquine and metrifonate. Surgery with decompressive laminectomy and debridement is usually reserved for cases of acute myelitis that deteriorate despite intensive schistosomicidal treatment.

Preventive measures in countries affected by schistosomiasis include the use of chemotherapy, snail control measures, and behavioral modification.

Viral Infections 69

Shibani S. Mukerji, Maria Martinez-Lage, and Kiran T. Thakur

KEY POINTS

1. Neurotropic viruses enter the central nervous system (CNS) using multiple mechanisms including neural and hematogenous pathways.
2. Introduction and propagation of vector-borne neurotropic viruses into immunologically naive populations can give rise to explosive infectious disease outbreaks.
3. Viral nucleic acid amplification and detection of virus-specific immunoglobulin M in cerebrospinal fluid and blood are common modes of diagnostic testing in CNS infections.
4. Mononuclear lymphocytic infiltrates in the subarachnoid space and perivascular spaces characterize meningitides.
5. Viral encephalitis commonly demonstrates multifocal perivascular and parenchymal lymphocytic infiltrates, which are typically T-cell predominant.
6. Therapeutic antiviral agents are few, and treatment in many CNS viral infections remains supportive.
7. Prevention is the best approach to combating viral diseases and requires vaccination programs, mosquito repellents, protective gear, animal surveillance programs, and education.

INTRODUCTION

Viral infections of the central nervous system (CNS) are a diverse group of diseases that have plagued mankind for centuries. Infections can occur in the spinal cord (myelitis), brain parenchyma (encephalitis), meninges (meningitis), brainstem (rhombencephalitis), or any of these in combination. Viral infections can cause damage directly in the CNS or via immune-mediated mechanisms. This chapter highlights the common causes of CNS viral infections (aside from human immunodeficiency virus [HIV], which is discussed in a separate chapter) and discusses the clinical manifestations and the methods of detection and management.

Viruses invade humans by a variety of mechanisms. This can include skin penetration, infection of mucosal membranes, or by direct inoculation into the bloodstream. After primary inoculation, neurotropic viruses gain entry into the CNS by one of a number of mechanisms. Experiments with several viral strains show that replication occurring in tissue, such as skeletal muscle or skin, allows access to peripheral nerve endings. Some neurotropic viruses are able to infect nerves and then spread by retrograde and anterograde transport to the sensory ganglia. Characteristic of this are the herpes viruses, which replicate in the skin and infect adjacent sensory nerve endings. The virus is then able to tether its capsid onto the host's transport complex, travel toward the dorsal root ganglia, and establish latency.

In contrast, infection within the bloodstream is dependent on the site of inoculation and ability to infect endothelial cells or cell populations within plasma (eg, HIV infection). Once in the blood, a virus must cross the blood-brain barrier (BBB) to spread into brain parenchyma. In cases like HIV, when infected inflammatory cells, such as lymphocytes or macrophage mononuclear cells cross the BBB, the virus gains entry in a process termed the *Trojan horse*. In other cases, high viremic loads lead to passive transport into the brain or spinal cord. Individual viruses can use multiple mechanisms of viral CNS entry, and in fact, many viruses are able to spread to the CNS using both neural and hematogenous pathways as will be discussed with poliovirus and varicella-zoster virus (VZV).

The widespread availability of viral nucleic acid amplification has revolutionized diagnostics in CNS viral infections and reduced the need to perform open brain biopsies. The polymerase chain reaction (PCR) technique is ideally suited for organisms that are difficult to culture and can retain its sensitivity even after small doses of antiviral therapies. However, this technique relies on a viral load high enough for detection by PCR, a factor not always present in cerebrospinal fluid (CSF), leading to false negatives. False negatives also occur when heme breakdown from a bloody lumbar puncture interferes with nucleic acid detection. False-positive CSF PCR results occur with viruses that associate themselves with peripheral blood cells and enter the CNS during an inflammatory process but are themselves not the source of the CNS disorder. This phenomenon occurs with Epstein-Barr virus (EBV), as peripheral blood mononuclear cells are latently infected. The EBV's relevance as a pathologic agent in the CSF can be unclear and is discussed further in this chapter.

Additional diagnostic methods for CNS viral infections include detection of virus-specific immunoglobulin (Ig) M that relies on the host's ability to mount an immunologic response to the infecting agent. The detection of virus-specific antibodies requires a competent immune system and sufficient time to develop antibodies. Interpretation of antibody levels can be confusing, as some serum antibodies last for months or even years after infection that is often asymptomatic, as seen in West Nile virus (WNV) where IgM-specific antibodies can persist for months and is not reflective of acute infection. Occasionally, antibody cross-reactivity can also lead to false-positive detection. In contrast to serum antibodies, the presence of virus-specific IgM antibodies in CSF is indicative of intrathecal synthesis and diagnostic of neuroinvasive disease.

Serum virus-specific IgG can be helpful when a corresponding rise in titer between acute and convalescent phases occurs. One limitation here is in the setting of postinfectious complications, where antibody detection in the acute phase was not pursued.

FIGURE 69.1 Common neuropathologic features of viral encephalitis. **A:** Luxol-hematoxylin and eosin-stained section of the basal ganglia shows dense perivascular and scattered parenchymal small round cells representing lymphocytic inflammatory infiltrates, characteristic of many viral infections. **B:** Luxol-hematoxylin and eosin-stained section of the pyramidal layer of the hippocampus shows neuronophagia, consisting of microglial cells and macrophages engulfing dying neurons. **C:** Luxol-hematoxylin and eosin-stained section of the dentate nucleus of the cerebellum shows two microglial nodules characterized by focal collections of small mononuclear microglial cells. Intranuclear inclusions of diverse morphology can be seen in a variety of viral central nervous system infections. **D:** Hematoxylin and eosin-stained section of the cerebral cortex in a patient with measles related subacute sclerosing panencephalitis shows the characteristic round eosinophilic inclusion with surrounding clearing halo in one cell. **E:** Luxol-hematoxylin and eosin-stained section of the cerebrum in a neonate with congenital cytomegalovirus encephalitis demonstrates typical intranuclear cytomegaloviral inclusions in multiple cells. **F:** Luxol-hematoxylin and eosin-stained section of the cerebral white matter from a patient with progressive multifocal leukoencephalitis demonstrates the glassy appearance of a viral intranuclear inclusion with a rim of dark chromatin in an enlarged glial cell containing John Cunningham virus particles.

Isolated IgG detection, especially in infections that are common and usually asymptomatic, is of limited use. Advanced diagnostic platforms including multiplex PCR and next-generation sequencing are laboratory techniques, which are being increasingly deployed to aid in diagnosis of viral CNS infections.

Although tissue assessment is uncommon in CNS viral infections, autopsy studies demonstrate certain patterns of involvement that can suggest an underlying viral encephalitis in an otherwise uncertain neurologic syndrome (Fig. 69.1). Mononuclear lymphocytic infiltrates in the subarachnoid space and perivascular (Virchow-Robin) spaces characterize all meningitides. Viral encephalitis commonly demonstrates multifocal perivascular and parenchymal lymphocytic infiltrates, usually T-cell predominant. Activated microglia with a focal distribution in the form of microglial nodules, and neuronophagia characterized by microglia and macrophages engulfing dying neurons are histologic features frequently associated with viral encephalitis. In certain specific viral infections, such as cytomegalovirus (CMV) or John Cunningham virus (JCV), characteristic abnormalities can be seen in infected cells called *viral cytopathic change*, namely, intranuclear inclusions or nuclear clearing, and rarely cytoplasmic inclusions. Multiple domains are frequently affected pathologically, such as cerebral gray or white matter, brainstem, spinal cord, spinal roots, and leptomeninges in diverse combinations. Although the pattern of viral encephalitis described is most common in many viral CNS infections, there are other potential histologic characteristics, such as necrotizing encephalitis in herpes simplex virus (HSV) infection, for example.

Antiviral agents are few in number, and treatment in many cases of CNS viral infections remains supportive. The HSV, VZV, CMV, HIV, and influenza have targeted therapies with varying efficacy. The lack of options in many cases leads physicians to focus on managing the complications of these diseases, often including use of anti-inflammatory agents, such as corticosteroids, to suppress immune-mediated injury. As seen in almost every aspect of medicine, prevention is the best approach to combating viral diseases and requires comprehensive vaccination programs, mosquito repellents, appropriate protective gear, animal surveillance programs, and education.

PICORNAVIRUS

Picornaviruses are some of the oldest and most diversified viruses to cause human disease. The picornavirus family has four primary groups resulting in human pathogenesis: enteroviruses

(eg, polioviruses, coxsackieviruses, and echoviruses), rhinoviruses, hepatoviruses (eg, hepatitis A), and parechoviruses. These viruses are nonenveloped, single-stranded RNA viruses. It is estimated that the majority of viral meningitis cases globally are caused by picornaviruses, specifically enteroviruses, as are most cases of acute flaccid paralysis.

Enteroviruses

Human enteroviruses, named for their transmission route via the intestine, contain a positive-sense, single-stranded RNA genome. Seventy-one human serotypes of enteroviruses exist and are classified into groups A, B, C, and D. Polioviruses are part of the human enterovirus C group, whereas the nonpolio enteroviruses include coxsackievirus A and B and various echoviruses and enteroviruses. Enteroviruses cause a wide range of symptomatology, with neurologic symptoms being the most serious.

Poliomyelitis

Poliomyelitis is a disease that plagued the world in the early 20th century, as widespread epidemics resulted in paralysis or death. The name *poliomyelitis* is derived from two Greek words, *polios* ("gray") and *myelon* ("marrow" or "spinal cord"). The control of polio following the development of both the inactivated polio vaccine (inactivated poliomyelitis vaccinations [IPVs]) and live-attenuated oral vaccines (oral poliomyelitis vaccinations [OPVs]) is a remarkable achievement in science, and since the launch of the Global Polio Eradication Initiative in 1988, the incidence of poliomyelitis has been reduced by over 95%, although global eradication has ongoing challenges. Poliomyelitis was declared a public health emergency of international concern in 2014 after there was international spread of poliovirus to a range of polio-free countries. War-torn regions are at particular risk, and at the beginning of 2019, Afghanistan and Pakistan were the only remaining two countries in which wild poliovirus transmission continues to be reported. Another challenge is the emergence of outbreaks of vaccine-derived poliovirus, rare strains that have genetically mutated from the poliovirus contained in the oral polio vaccine. The recently published Polio Endgame Strategy 2019-2023 by the World Health Organization (WHO) addresses three key risks associated with global wild poliovirus eradication including insecurity and conflict; weak or fragile health systems; and operational, management, and resource risks.

Pathobiology

Poliomyelitis virus main route of human infectivity is via the gastrointestinal tract, although during epidemics, humans can be infected via pharyngeal spread. Infectious spread is highly influenced by hygiene standards. All three serotypes of poliovirus are neurotropic, although poliovirus type 1 is the most frequently encountered in human infections around the world. Although the disease occurs in all age groups, it is rarely seen before 6 months of age. Previously, poliomyelitis was endemic and widespread immunity occurred in babies due to protection through maternal antibodies. However, given the lack of endemic poliomyelitis, immunity no longer exists and vaccination strategies are key to elimination.

Viruses multiply in the pharynx and intestine during an incubation period, which typically occurs over a few weeks, before there is bloodstream involvement. The virus replicates initially in the gastrointestinal tract's lymphatic system (Peyer patches), followed by viremia and immune activation. How the virus gains access to the nervous system remains uncertain. One hypothesis is the poliomyelitis virus, which is able to replicate in skeletal muscles, can spread into peripheral motor axons and access anterior horn cells of the spinal cord via retrograde transport. This hypothesis has been tested in mouse models with expression of transgenic poliomyelitis virus receptor. A second hypothesis is by direct spread from the blood due to a breakdown in the BBB. These mechanisms for CNS entry are not mutually exclusive. Viral replication in the CNS leads to motor neuron death associated with inflammatory infiltrates (initially polymorphonuclear cells and later lymphocytes) and neuronophagia, consisting of microglia and macrophages engulfing dying neurons. Retrograde transport leads to further neuronal injury.

Clinical Manifestations

Although CNS complications are the most feared and well-known result of polio infection, it is a not a common occurrence when evaluating poliomyelitis infections as a whole. Nearly 90% of infections are asymptomatic and recognized only by isolation of the virus from the oropharynx or in feces. Approximately 4% to 8% of those infected will have a minor, self-limited illness such as other enteroviral infections with headache, anorexia, abdominal pain, and a sore throat. These cases are typically identified during epidemics. In 1% to 2% of infected individuals, fever, headache, and meningismus occur. Frank paralysis occurs in only 0.1% of all poliovirus infections, and the clinical course can be divided into two phases. A prodromal phase of sore throat, fever, and upper respiratory infection symptoms is most common in young patients. Mild gastrointestinal symptoms and meningeal irritation are more common in adults. There is a short recovery period for 2 to 3 days before an abrupt onset of fever, chills, myalgias, headache, and symptoms consistent with meningitis. Paresthesias and muscle fasciculations can precede muscle weakness and paralysis. When paralysis occurs, it is typically asymmetric, and the lower extremities are more commonly involved than the upper extremities. When quadriplegia occurs, it is more frequently seen in adults than in infants. Paralysis of the diaphragm and intercostal muscles in spinal poliomyelitis occurs more often in young adults than in the extreme age groups. Bulbar paralysis is due to weakness of muscle groups innervated by cranial nerves, and in polio, the glossopharyngeal and vagus nerves are most commonly affected, followed by the oculomotor nerve. Older adults are more likely to have medullary involvement, and these patients are at high risk for aspiration and need for mechanical ventilation.

Diagnosis

The diagnosis of paralytic polio is clinically suspected with the development of asymmetric acute flaccid paralysis following a febrile illness. It is more likely to be suspected in those who are unvaccinated coming from endemic countries or those with immunodeficiencies. Other viruses to consider in the differential are other enteroviruses, especially enterovirus 71, and arboviral infections, such as WNV (discussed later in the chapter).

The CSF pleocytosis is evident as early as meningeal symptoms are present, with an initial polymorphonuclear profile that eventually shifts to a lymphocytic predominance. An increased protein concentration is most prominently seen if there is severe paralysis. These abnormalities are not distinguishable from other viral causes of aseptic meningitis, and thus, identification of the poliomyelitis virus is necessary to confirm the diagnosis. Isolation of poliomyelitis virus by CSF culture is challenging and is not typically performed. Polio is more easily isolated from

oral secretions and feces, and with rapid identification of polioviruses by genomic amplification using PCR, clinicians can distinguish poliomyelitis viral infections from other enteroviruses or other infectious causes.

Treatment

There are no antiviral drugs for treatment of poliomyelitis, and symptom management is the primary focus. Respiratory muscle paralysis or cases of bulbar poliomyelitis frequently require mechanical ventilation and aggressive management of secretions. Bowel function also requires special attention in spinal poliomyelitis. Long-term management of physical and psychiatric sequelae obliges a comprehensive team of both physical and occupational therapy along with orthopedic services and psychiatry.

The IPV and OPV have been used effectively for controlling paralytic poliomyelitis but differ in terms of asymptomatic viral shedding and risk of contracting vaccine-related disease. The IPV is an injectable preparation containing antigen units for all three polio serotypes. In the United States, the IPV is the only version administered and is typically given with other childhood vaccines at 2, 4, 6 to 18 months, and 4 to 6 years. Children develop little to no secretory antibody response to the IPV. If exposed to live polioviruses, these children are more likely to have asymptomatic infections but still shed virus in their feces, exposing nonimmunized contacts. Most OPV preparations also immunize against all three serotypes. The prevalence of poliomyelitis-specific antibody to all three serotypes following three doses of OPV is approximately 96%. Nonimmune OPV recipients will shed vaccine viruses in feces and the oropharynx that can be spread to nonimmunized children. This aspect can be advantageous in poorly vaccinated communities, as children can develop OPV-specific antibodies despite not having received the vaccine. A rare event is the development of vaccine-associated paralytic poliomyelitis, an occurrence in 1 per 2.6 million vaccine doses and is only associated with OPV. This is more commonly seen in immunodeficient patients. Vaccine-derived poliomyelitis refers to outbreaks of acute flaccid paralysis caused by circulating poliovirus strains derived from one of the three Sabin poliovirus strains in OPV. This occurs in regions where there are low immunization rates which allowed the vaccine-derived poliovirus to mutate and to acquire biologic properties similar to those of naturally occurring wild-type polioviruses. The WHO still recommends the use of the trivalent OPV in underdeveloped nations because of cost, ease of administration, and greater secretory immunity in the gastrointestinal tract.

Outcome

The prognosis of paralytic poliomyelitis depends on age (infants and children are more likely to recover) and severity of paralysis (ie, partial vs complete paralysis). Permanent weakness from polio paralytic infections occurs in approximately two-thirds of patients. Complete recovery is unlikely in cases with severe acute flaccid paralysis or in those requiring mechanical ventilation. Increased mortality is typically seen in those with polio encephalitis, bulbar involvement due to glossopharyngeal and/or vagus nerve impairment, and/or respiratory muscle paralysis.

Following the epidemics in the early 20th century, some individuals with partial or full recovery from paralytic polio experienced a new onset of neuromuscular weakness, pain, and fatigue. In such cases, muscle weakness and atrophy were identified in muscles that had been previously affected. Management is symptomatic and supportive and typically involves a multidisciplinary approach. These symptoms have been collectively called the *postpolio syndrome* and, in those with slowly progressive weakness, atrophy, and fasciculations, termed *postpolio progressive muscular atrophy* (discussed separately). The cause of progressive neurologic deterioration is unknown, but contributing factors include ongoing damage of reinnervated motor units, persistence of poliovirus in nerve tissue, and secondary autoimmune destruction of neural structures. Evidence suggests that reinnervated motor units are perhaps that excessive exercise or overuse may predispose to new weakness.

Enterovirus D68

Enterovirus D68 is unique among enteroviruses in that it behaves biologically more like human rhinoviruses because it optimally grows at 33°C and is both heat and acid labile. Given these features, enterovirus D68 is transmitted primarily via respiratory rather than fecal-oral route. Although enterovirus D68 was first isolated in 1962 from respiratory specimens in four children with lower respiratory tract infections, it has not been until recent history that it has been associated with neurologic manifestations. In August 2014, there was an outbreak of respiratory illness predominantly in children due to enterovirus D68 in western United States. Beginning in 2012, an increasing number of cases of acute flaccid paralysis associated with spinal cord motor neuron lesions were reported in the United States, and then in 2014, a cluster of children with acute flaccid paralysis presented in the midst of an enterovirus D68 respiratory outbreak. Since the initial descriptions, there have been biannual peaks in cases characterized by acute flaccid weakness, with associated gray matter spinal cord lesions, typically longitudinally extensive. In the summer and fall of 2018, cases peaked with 230 confirmed cases in 41 states. Most have occurred approximately 1 week after a prodromal illness. Like poliomyelitis, most patients report clinical improvement in their prodromal illness before the patient often develops meningeal signs, followed by extremity weakness, often with respiratory muscle involvement. There is significant morbidity associated with specific enteroviral strains, including enterovirus D68. The Centers for Disease Control and Prevention (CDC) detected coxsackievirus A16, enterovirus A71, and enterovirus D68 in the spinal fluid of 4 of 563 confirmed cases of acute flaccid myelitis since 2014. Additional patients with acute flaccid myelitis were diagnosed with enterovirus D68 infections using respiratory samples.

Enteroviruses 70 and 71

Acute hemorrhagic conjunctivitis was first recognized in 1970 and is the result of either enterovirus 70 or an antigenic variant of coxsackievirus A24. The disease is characterized by the rapid onset of painful conjunctivitis and subconjunctival hemorrhage. Complete recovery is typically seen within 1 to 2 weeks. Epidemics predominantly occur in tropical and subtropical regions in Southeast Asia and Africa. Associated with cases of acute hemorrhagic conjunctivitis are cases of an often asymmetric acute flaccid paralysis. Those affected appear clinically similar to those with spinal poliomyelitis except for the preceding association with acute hemorrhagic conjunctivitis. Prodromal symptoms for acute hemorrhagic conjunctivitis-associated paralysis include fever and malaise then an acute, severe radicular pain. This is followed by flaccid, asymmetric weakness of the legs with proximal muscles (eg, quadriceps muscle) more affected. Reflexes are diminished or absent. Clinically, as in other enteroviruses,

the main lesion is believed to be in the anterior horn cells of the spinal cord and the cranial motor neurons. Permanent paralysis or residual weakness is present in over half the cases. The virus is difficult to isolate in the CSF by PCR when neurologic symptoms arise, but high titers of virus-specific antibodies are typically detectable in the CSF and/or serum in those with paralysis.

Clinically, enterovirus 71 is associated systemically with hand-foot-and-mouth disease in children and neurologically can present with acute flaccid paralysis, encephalomyelitis, or a rhombencephalitis. Enterovirus 71 is the etiologic agent responsible for several encephalitis epidemics throughout the world, resulting in substantial mortality and morbidity. The largest enterovirus 71 epidemic occurred in Taiwan in 1988, resulting in 1.5 million people affected, of which 405 children developed serious neurologic complications with 78 deaths. Every 2 to 3 years, large enterovirus 71 outbreaks occur around the Asia-Pacific rim, affecting thousands. As such, enterovirus 71 is now recognized as an emerging neurotropic virus. Enterovirus 71 can cause hand-foot-and-mouth disease as well as upper respiratory infections and gastroenteritis. In those affected neurologically, manifestations include myoclonic jerks, tremors, ataxia, cranial nerve palsy, meningitis, and meningoencephalitis. Polio-like flaccid paralysis occurs in about 10% of patients. Fulminant neurogenic pulmonary edema and apnea from rhombencephalitis occurred in epidemics affecting children in Taiwan and Malaysia, and these disease manifestations are the primary cause of death in enterovirus 71-infected individuals. Most of the patients had magnetic resonance imaging (MRI) T2-weighted high-intensity lesions in the brainstem. In Catalonia, Spain, an outbreak of brainstem encephalitis and encephalomyelitis occurred in 2016 with a new strain of enterovirus 71. The new strain was associated with a high degree of neurotropism of the virus. Diagnosis may be made by virus isolation from throat, feces, or vesicles; by antibody studies; and CSF reverse transcriptase polymerase chain reaction (RT-PCR). Treatment is supportive, and patients are often administered intravenous immunoglobulin (IVIG) and/or plasma exchange with mixed results.

Coxsackievirus and Echoviruses

Although most infections are mild or asymptomatic, neurologic manifestations of human viral infections caused by group A and B coxsackieviruses and echoviruses primarily are meningitides. Historically, group B coxsackieviruses and echoviruses are the most frequently implicated serotypes in meningitis; exceptions include when a single serotype causes a widespread outbreak. For example, coxsackievirus A9 was responsible for most cases in an outbreak in the Gansu Province, China, in 2005 and Alberta, Canada, in 2010.

The symptoms and signs of meningeal involvement of coxsackieviruses and echoviruses are similar to other viruses that cause meningitis. The severity of disease varies, with the extremes of life having the more severe meningitis. Headache is frequent, and if meningismus is present, it can vary in severity and typically begins 24 to 48 hours following onset of symptoms. In infants, the dominant symptoms are fever and irritability, with less than 10% having evidence of meningeal irritation. Frequently, there is a prodromal or associated upper respiratory tract infection or symptoms. Acute CNS complications include febrile seizures, elevated intracranial pressure, and coma. When considering alternate diagnoses for enterovirus meningitis, bacterial meningitis needs to be considered and should be treated empirically with broad-spectrum antibiotics. Commonly, adults will have associated myocarditis and pericarditis, and all patients should undergo cardiac evaluation.

Although encephalitis is not commonly caused by coxsackievirus or echovirus (except for enterovirus 71), it can occur in immunocompromised patients. The severity of encephalitis is variable, with seizures, hemichorea, and acute cerebellar ataxia being described. In patients with agammaglobulinemia, hematopoietic transplantation, or B-cell depletion with immunotherapy agents, enterovirus can cause a chronic, severe, and fatal meningitis and encephalitis. In such cases, enterovirus can be recovered in the CSF by PCR at different time points throughout the disease course. The IVIG and pleconaril have been used with some success.

Sporadic cases of acute flaccid paralysis have been seen with coxsackieviruses and are typically less severe than in poliovirus associated disease. For example, in an 11-year program monitoring of acute flaccid paralysis in the Slovak Republic as part of the WHO strategy for polio eradication, coxsackievirus B and echoviruses were the most common etiologies for acute flaccid paralysis in the post–polio vaccine era. These viruses are also reported etiologies for oculomotor palsies, Guillain-Barré syndrome (GBS), opsoclonus-myoclonus, and transverse myelitis.

The CSF analysis typically demonstrates clear fluid with normal to mildly elevated pressure. There is a mild to moderate pleocytosis that ranges from 10 to 500/mm^3 and rarely exceeds 1,000/mm^3. Initial differential cell counts demonstrate a high percentage of neutrophils but an eventual shift to a lymphocytic predominance. The CSF glucose concentration is generally normal and protein concentrations are normal to slightly elevated. PCR is the primary means of virus detection with greater than 95% sensitivity and specificity.

Containment during outbreaks is critical, with good hygiene practices and protective equipment for high-risk groups. The broad-spectrum antipicornaviral agent pleconaril is an orally administered inhibitor of enterovirus replication. There have been two placebo-controlled clinical trials that showed a shortened course of illness compared to placebo, but the benefit was modest. The drug has not been approved for use in the United States.

ARBOVIRUSES

Arthropod-borne viruses (arboviruses), as their name implies, are transmitted to humans through the bites of infected mosquitoes and ticks. A bite from an infected mosquito can infect with WNV, La Crosse, Jamestown Canyon, St. Louis encephalitis, and eastern equine encephalitis (EEE) viruses, and ticks can transmit Powassan virus. In symptomatic people, both nonneuroinvasive and neuroinvasive infection occurs. In the United States, WNV is the leading cause of arboviral disease. Human infection due to arboviruses follows patterns of vector activity. Seasons and years when the insects are most abundant logically see higher rates of infections. Most arboviruses have vertebrate reservoirs, such as birds or small mammals, and are transmitted by mosquitoes or ticks. Continuation of the life cycle relies on a constant interaction between hosts (eg, birds, mammals) and vectors (eg, ticks, mosquitoes). Animals that act as hosts maintain high enough levels of viremia and can retransmit infections back to arthropods when bitten. However, humans and horses are "dead-end" hosts, as they are not able to sustain elevated levels of viremia without succumbing to disease. Endemicity varies widely, as do outcomes. Neurologically, patients can present with meningitis, myelitis,

and/or encephalitis. Less common neurologic syndromes can include cranial and peripheral neuritis or other neuropathies, including GBS. Neuroinvasion is usually coupled with an intense inflammatory reaction and/or edema, the effects of which can be devastating. Alternatively, neurologic disease can occur as a parainfectious inflammatory disorder in the setting of systemic disease without specific evidence of nervous system infection per se. Fortunately, for the most part, exposure leads to asymptomatic seroconversion or a mild self-limited illness; typically, only a fraction progress to severe neurologic disease and/or death.

Acute arboviral infections are diagnosed typically by serum and/or CSF antibody detection via enzyme-linked immunosorbent assay for virus-specific IgM antibodies. Given the high prevalence of asymptomatic infection and potential for persistence of IgM in serum, antibody detection must be confirmed with a fourfold titer increase in IgG between the acute and convalescent phase (4 weeks after the acute phase). In general, though, the presence of CSF virus-specific IgM antibodies is indicative of intrathecal synthesis and is diagnostic for neuroinvasive disease. The CSF RNA detection is highly specific for active infection, but its sensitivity in arboviral infections is not nearly as high as seen in herpes simplex DNA detection. The CSF PCR can be especially helpful in immunocompromised people who are unable to mount or have a delayed antibody response. Culturing arboviruses is not routinely performed, as they are difficult to isolate due to low levels of viremia in humans. There are no specific antiviral therapies for the treatment of neuroinvasive arboviral infections and the focus remains on supportive care and exposure prevention. Anecdotally, people have been treated with IVIG, especially in the context of WNV neuroinvasive disease.

Flaviviruses

Flaviviruses are positive-sense, single-stranded RNA, enveloped viruses with icosahedral capsids. The most well-known members include dengue virus (DENV), yellow fever virus, Zika virus and WNV. Most are transmitted by biting arthropods, usually mosquitoes or ticks (**Table 69.1**).

Dengue

Dengue is the second most common mosquito-borne disease affecting human beings. There are four serotypes of this flavivirus, and infection with one does not confer protection from infection with the others. All serotypes can cause severe disease, including neurologic manifestations, although serotypes 2 and 3 most commonly lead to neuroinvasive disease. Dengue is carried by the *Aedes* species of mosquito and is endemic in most tropical and subtropical regions, with the highest reported incidence in Asia and Central and South America. As with other flaviviruses, inoculation proceeds to local immune cell infection and carriage to a lymphatic center, where replication occurs and viremia results. The virus makes its way to the CNS, although mechanisms of infection are not well understood. Virus is detected in the CNS, although it is not known if this occurs passively across an altered BBB or as an active infection. Vasogenic edema results, and a systemic inflammatory response can elicit immune-mediated damage of multiple organs and the neuraxis.

After exposure and subsequent incubation of several days to just over a week, those who are symptomatic will experience fever, myalgias, and malaise most commonly, occasionally with a rash. Severe systemic disease can follow over a matter of days, characterized by thrombocytopenia, multifocal hemorrhage, shock, and death. Neurologic manifestations can accompany severe disease and range from encephalopathy to direct nervous system infection accompanied by an inflammatory response causing meningoencephalitis and/or myelitis to a parainfectious immune diseases such as GBS and acute disseminated encephalomyelitis (ADEM). Acute encephalopathy is the most common neurologic syndrome associated with DENV, often precipitated by systemic shock. Risk factors for developing severe disease include young age, certain human leukocyte antigen genotypes, female gender, and superinfection with a second serotype.

Diagnosis

Given the protean neurologic complications, there is no specific neuroimaging finding related to dengue, and computed tomography (CT) or MRI of the brain may be entirely normal. Similarly, CSF may be normal or only demonstrate elevated protein concentration depending on the neurologic syndrome. In DENV-associated encephalopathy, the CSF basic profile is typically normal, whereas opening pressures can be elevated. If there is a pleocytosis, it is generally lymphocytic. If caught early, RNA can be detected from the blood and/or CSF; otherwise, antibody detection from blood and/or CSF demonstrating active or recent production is diagnostic. However, cross-reactivity is frequent with other flaviviruses. In endemic areas, a tourniquet test to assess capillary fragility can be performed at the bedside in the appropriate clinical context to make a presumptive diagnosis.

Treatment

No vaccine or specific therapies exist for dengue infection, although aggressive supportive treatment early on, with platelet transfusions, rehydration, and management of elevated intracranial pressure, may improve survival. Although there is little data to support such treatment, some have used steroids, and IVIG in patients with neurologic effects from dengue. Overall, case fatality rate is 4% to 5%, although some 25% of survivors will suffer residual neurologic deficits (see **Table 69.1**).

Tick-Borne Encephalitis Virus

Tick-borne encephalitis virus is carried by the Ixodes tick. Tick-borne encephalitis is endemic in 19 European countries and parts of Asia, with a significant amount of infections noted in Russia, and is responsible for thousands of infections each year. Men are more commonly affected than women. Viral infection results in replication in lymphatic cells, vascular dispersion, and entry into brain parenchyma by means of brain microvascular endothelial cells. Viral presence in the brain incites an inflammatory reaction that precipitates widespread damage throughout the cerebrum, cerebellum, brainstem, and sometimes the spinal cord. After an incubation period of about a week, patients develop a fever that lasts several days and in the second phase of illness progresses to headache, nausea, and occasionally meningismus. A severe encephalitis developed in approximately half of patients. Associated spinal cord inflammation sometimes occurs, often presenting as a flaccid paralysis due to anterior horn cell involvement. Diagnosis is best made by demonstration of intrathecal tick-borne encephalitis virus-specific antibody production; serum antibodies can be useful in the patient who has never received vaccination. As with other flavivirus infections, cross-reactivity is common with antibody testing. The CSF usually shows a modest lymphocytic pleocytosis, which transitions to monocytic and elevated protein concentration, although in some cases, a polymorphonuclear pleocytosis has been demonstrated.

TABLE 69.1 Nervous System Disease Caused by Flaviviruses

Virus	Endemic Locale	No. of Infections Annually	Systemic Symptomatic Disease (% of Infections)	Neurologic Disease (% of Symptomatic Infections)	Neurologic Manifestations	Case Fatality Rate	Long-term Sequelae	Preventive Strategies
Japanese encephalitis virus	Southeast Asia, Japan, Pacific Islands	30,000-50,000	0.30	0.001-0.02	Encephalitis with brainstem and occasionally spinal cord involvement	25%	30%	Vector control, vaccine
West Nile virus	Africa, Middle East, Continental United States, Puerto Rico	~150,000 (United States)	20	1	Meningoencephalitis and/or acute flaccid paralysis	10% overall, 15%-30% in age older than 70 y	50%	Vector control, blood and organ donation restrictions
Dengue virus	Central and South America, Puerto Rico, Africa, Middle East, India, Southeast Asia, Pacific Islands, Northern Australia	50-400 million	0.5-1	4-50	Meningoencephalitis, ADEM, GBS, CNS hemorrhage	4%-5%	~25%	Vector control
Murray Valley encephalitis virus	Northern Australia, New Guinea	Occurs in outbreaks	Outbreaks of 21-114 cases	0.1-0.7 of all infections	Meningoencephalitis	20%-40%	30%-50%	Vector control
Tick-borne encephalitis virus	Europe, Southern Russia, East Asia	~35,000	2-33	25-30	Meningoencephalitis	1%-2% (Western Europe), 30%-40% (Eastern Russia)	35%-60%	Vector control, vaccine
Kunjin virus	Northern Australia, New Guinea	Occurs in outbreaks	Minority	Minority	Mild meningoencephalitis or encephalomyelitis	<1%	NA	Vector control
St. Louis encephalitis virus	Continental United States	~1,000; higher in outbreaks	<1	>60	Meningoencephalitis	5%-15%	Up to 50%	Vector control
Powassan virus	Canada, Northern United States, Russia	NA; seroprevalence 0%-5% in endemic areas	Minority	NA; <50 cases reported 2001-2018 but incidence rising	Meningoencephalitis and/or encephalomyelitis	10%	50%	Vector control

Abbreviations: ADEM, acute disseminated encephalomyelitis; CNS, central nervous system; GBS, Guillain-Barré syndrome; NA, not applicable.

Treatment of tick-borne encephalitis virus is supportive. Mortality varies by location, at 1% to 2% for Western Europe but up to 40% for Eastern Russia (see **Table 69.1**). Long-term neuropsychiatric sequelae occur in more than half of the survivors.

Japanese Encephalitis Virus

Japanese encephalitis (JE) virus is transmitted by the *Culex* mosquito. The JE virus is the most commonly diagnosed epidemic encephalitis in the world and is found throughout South and Southeast Asia (see **Fig. 69.1A**). Like its sibling flaviviruses, initial replication is in lymphoid tissue followed by transient viremia that carries the virus to the brain; once inside the CNS, it imparts damage both by infection and reactive inflammation. Unlike many other flaviviruses, neurologic manifestations occur in the majority of patients who are symptomatic.

In symptomatic cases, after an incubation period of a little over a week, fever sets in, along with chills, myalgias, and occasionally meningismus. In children, abdominal pain and nausea are common. Symptoms can quickly progress to limb weakness and extrapyramidal signs and subsequently to coma and death. Imaging and pathologic specimens show thalamic and cerebral peduncular involvement, but viral involvement is typically widespread throughout the brain and even into the spinal cord occasionally. Parkinsonian features may be significant; other movement disorders include lip smacking, bruxism, choreoathetosis, and hemiballismus. Poliomyelitis-like flaccid paralysis indicates damage of anterior horn cells in the spinal cord, and cranial nerve signs include facial palsies, ptosis and abnormalities of eye movements. Obvious generalized tonic-clonic seizures can occur, and subtle motor seizures can also be observed in some instances, especially in advanced disease in children. The CSF typically shows a lymphocytic pleocytosis of up to 1,000 cells/μL and a modestly increased protein concentration. Diagnosis is usually by antibody detection from CSF or by serologic increases between acute and convalescent phases; RNA isolation from CSF is diagnostic as well. As with other flavivirus infections that are usually asymptomatic and/or have vaccines available, a single positive IgG in endemic areas may not indicate active disease.

Treatment is supportive, keeping in mind that death commonly is secondary to cerebral edema and increased intracranial pressure. Of those who survive, about 30% will have long-term deficits (see **Table 69.1**), again making prevention strategies key. These include vector control and vaccination; however, vaccine use has resulted in a decrease in JE virus incidence in many Asian countries, but estimates suggest that 80% of cases still occur in areas with JE virus vaccine programs. This is likely multifactorial including possible waning immunity and vaccine ineffectiveness and problems with the cold chain.

West Nile Virus

The WNV was originally isolated in Africa, but since introduction to New York in 1999 which led to an outbreak, the virus has been endemic in the United States (see **Fig. 69.1A**). The WNV has a worldwide distribution with outbreaks identified throughout the globe. Its vector is the *Culex* mosquito, although infected donated blood has been another mode of transmission. As of 2012, all 48 contiguous states in the United States had reported cases. Most cases of WNV are asymptomatic and go unreported; there were an estimated 1.8 million infections in North America between 1999 and 2010. Hundreds to thousands of symptomatic cases are reported to the CDC each year. As such, seroprevalence of WNV IgG in endemic areas is actually quite high. Of the symptomatic cases, the most common symptoms are fever and malaise. Less than 1% will go on to develop what is considered neuroinvasive disease: meningitis, encephalitis, or myeloradiculitis. Risk factors for developing neuroinvasive disease are age older than 50 years, immune suppression, homelessness, chronic renal disease, hepatitis C infection, and CCR5 mutations.

The WNV has an incubation period of 2 to 14 days, after which replication occurs in lymph tissue, followed by viremia and carriage to the CNS, where it infects neurons and anterior horn cells. How it does so remain elusive, as receptors have not been identified, nor is it known how the virus crosses the BBB. As with many viral CNS diseases, though, its mechanism of neuronal injury and death is directly related not only to viral infection but also to the intense inflammatory reaction that imparts bystander damage to the delicate resident cells in the brain and spinal cord.

The majority of individuals infected by WNV do not have symptoms or a febrile illness. Neuroinvasive disease occurs in less than 1% of WNV cases, although may be underreported. The WNV neuroinvasive disease may present as West Nile meningitis, West Nile encephalitis, or acute flaccid paralysis. New parkinsonism points to basal ganglia involvement and is seen commonly in patients with WNV encephalitis. Detection of IgM antibody in serum or CSF is the diagnostic test of choice. Because IgM antibody does not cross the BBB, its presence in CSF indicates CNS infection. Most patients with meningoencephalitis have IgM antibodies in CSF by about 1 week after symptom onset and IgG testing has no utility in patients with acute neurologic symptoms. Recent vaccination with other flaviviruses or recent infection with a related flaviviruses may produce a positive WNV-IgM antibody result. The plaque-reduction neutralization test can help distinguish serologic cross-reactions among the flaviviruses, but the test is only available in reference laboratories and takes a significant amount of time to return.

As with many viruses, WNV is a monophasic illness for which there is no proven specific therapy other than supportive therapy. An IVIG, a WNV-specific IgG, and a ribavirin all have been not clearly beneficial though have been used anecdotally. Long-term sequelae are the rule for survivors of neuroinvasive disease especially those with encephalitis, and about 10% die (see **Table 69.1**), making prevention of mosquito bites the most logical management strategy. No vaccine is available for WNV.

Murray Valley Encephalitis Virus

Murray Valley encephalitis virus is carried by the *Culex* mosquito and is endemic to Northern Australia and Guinea. It mostly has occurred in outbreaks with case numbers in the teens to low hundreds, making it much less of a threat than most other flaviviruses, especially those with a global presence. At least four outbreaks may have occurred in the early part of the 20th century under the moniker "Australian X" disease, and in 1951, the virus was isolated during the first documented Murray Valley encephalitis virus outbreak. Subsequent outbreaks occurred in 1956, 1974, and 2011. The 2011 outbreak was associated with high seasonal rainfall and flooding, serving as a nidus for increased mosquito vectors. There have been sporadic cases additionally. Given its outbreak potential, Murray Valley encephalitis virus is a "notifiable" disease in all Australian states and territories.

Incubation time averages 2 to 4 weeks. The vast majority of cases is asymptomatic or gives rise to a mild febrile illness with headache that does not come to medical attention. About 1 out

of 150 to 1,000 infections develop more severe symptoms several days later of lethargy, encephalopathy, and occasionally seizures that can progress to brainstem symptoms, flaccid paralysis due to myelitis, and death. The case fatality rate is 15% to 30%, and about 30% to 50% suffer long-term neurologic deficits (see **Table 69.1**).

In severe cases, T2-weighted MRI of the brain shows bilateral thalamic and brainstem hyperintensities, similar to other flaviviruses. Pathologically, virus has been recovered from brain tissue, and additionally, there is a striking widespread reactive inflammatory infiltrate throughout the gray matter. Diagnosis is often by serology, suggesting that specific Murray Valley encephalitis virus IgM appears several days after infection and persists for months. Antibodies can also be evaluated in CSF, as well, and there are Murray Valley encephalitis virus RNA assays for detection in serum. Management is supportive.

St. Louis Encephalitis Virus

St. Louis encephalitis virus is carried by *Culex* species mosquitoes and is a cause of epidemic encephalitis in both North and South America but mostly in the United States. Epidemics typically occur during the summer season. The vast majority of individuals have asymptomatic infections. Otherwise, presenting symptoms mimic a flulike illness and include fever, headache, and lethargy. Neurologic features can include seizures, ataxia, confusion, hemiparesis, and myoclonus.

The CSF analysis demonstrates a predominantly lymphocytic pleocytosis. St. Louis encephalitis virus is rarely isolated from blood or serum and diagnosis largely requires demonstration of St. Louis encephalitis virus-specific CSF IgM. An MRI can show T2-hyperintensities in the basal ganglia, and in some cases, abnormal signal is seen within the substantia nigra. Similar to other arboviral encephalitis, St. Louis encephalitis virus pathologic findings include perivascular, meningeal, and capillary lymphocytic infiltrates and activated microglia in gray and white matter. There are widespread neuronal degenerative changes, more obvious in cortex, basal ganglia, and cerebellum. A few St. Louis encephalitis virus cases have evidence of inflammation and neuronal loss in the spinal cord.

Treatment is supportive. Mortality varies considerably in case series and has been reported as high as 20%; long-term morbidity occurs in up to 50% of cases (see Table 69.1). Prognosis is worse with those who develop seizures.

Powassan Virus

This flavivirus is carried by the *Dermacentor* species and *Ixodes* ticks and is endemic in Canada, the northern United States, and far east Russia. It derives its name from the town in Canada where disease was first identified in 1958. Powassan virus is an emerging tick-borne illness with 2 US neuroinvasive cases identified in 2008 to 33 US cases identified in 2017. Symptoms occur after an incubation period of 1 to 4 weeks and begin with malaise, fever, and pharyngitis but can progress to hemiplegia, vomiting, marked brainstem dysfunction, coma, and death. The CSF studies, as with nearly all viral encephalitides, usually demonstrate a moderate lymphocytic pleocytosis and modestly elevated protein concentration. The gold standard for diagnosis is a screening Powassan antibody test followed by a confirmatory plaque reduction neutralization test, and referral to state laboratories in the United States is advised. Other tick-borne–related infections should be ruled out.

Pathologic studies demonstrate intense lymphocytic infiltrates and necrosis of gray matter mostly in the basal ganglia, thalamus, and mesial temporal lobes, corresponding to areas of abnormal brain MRI T2 hyperintense signal, although involvement is widespread (Fig. 69.2). There is no specific therapy

FIGURE 69.2 **Left panel:** Axial brain magnetic resonance images show focal T2-weighted/fluid-attenuated inversion recovery hyperintensities of the bilateral thalamus (**panel I**, *arrowheads*) and cortex (**panel I**, *asterisk*) and confluent hyperintensities of the cerebellum (**panel II**, *arrowheads*). Hematoxylin and eosin staining of a posterior fossa biopsy performed shows extensive lymphocytic infiltration and thickening of dura and diffuse inflammation of the cerebellum (**panel III**). The CD3 staining of the cerebellum reveals a predominantly T-cell lymphocytic infiltrate in the granule cell and molecular layers (**panel IV**). Scale bar = 100 μm. **Right panel:** Phylogenetic tree of Powassan virus genomes. Branches are labeled with the location, date, source, and GenBank ID of each Powassan virus genome. Nodes with at least 80% bootstrap support are labeled with percentage of bootstrap support. (Modified from Piantadosi A, Kanjilal S, Ganesh V, et al. Rapid detection of Powassan virus in a patient with encephalitis by metagenomic sequencing. *Clin Infect Dis*. 2018;66[5]:789-792, doi:10.1093/cid/cix792.)

for this disease, and treatment is supportive, although isolated cases have treated with IVIG. About half of the survivors suffer permanent sequelae (see Table 69.1).

Bunyaviruses

Bunyaviruses are negative-sense, single-stranded helical RNA viruses that are encapsulated. Although some are arboviruses, several are spread by rodents and are not associated with significant neurologic disease. Those that do result in encephalitis have less epidemiologic significance than most of the flaviviruses, which are found in densely populated areas, are widespread globally, and/or are much more neurovirulent.

Lacrosse Virus

Lacrosse virus is transmitted by the *Aedes triseriatus* mosquito. Lacrosse virus is endemic to the United States, and symptomatic cases are most commonly seen across the Ohio River Valley, mid-Atlantic, and Midwest. In these areas, the incidence is about 10 to 30 per 100,000 population, but only about 0.3% to 4% are symptomatic. Most cases are reported in children.

Initial infection causes viral replication in muscle followed by viremia and CNS invasion. The mechanism of entry into the CNS is unknown, but neurons and glial cells in the frontal, temporal, and parietal lobes are mostly affected. Presentation is of headache and fever, which progresses over days to seizures and encephalopathy about 25% to 50% of the time. The CSF demonstrates a lymphocytic pleocytosis with modestly elevated protein concentration, although results can be entirely normal. Lacrosse virus encephalitis presents similarly to herpes simplex virus encephalitis (HSE). Lacrosse virus IgM in CSF is diagnostic; otherwise, diagnosis comes from fourfold increase in IgG antibody titers from acute to convalescent phase. Alternatively, antigen detection on biopsy specimen provides the diagnosis. Treatment is supportive and the disease monophasic; mortality is less than 1%. If concern for HSE, treatment with acyclovir should be started immediately, until this is ruled out by CSF HSV PCR testing. Although there is a lack of evidence for its efficacy, ribavirin has been used on a compassionate use basis.

Jamestown Canyon Virus

This virus infects many species of mosquitoes and flies and is found throughout the United States into Canada. It is a rare cause of meningoencephalitis but is considered an emerging disease and likely underdiagnosed. Symptoms mirror those of other arboviruses, with onset of a mild febrile illness followed by severe headaches. Serologic studies are diagnostic when a fourfold rise in IgG is seen between acute and convalescent phases; treatment is supportive.

Togaviruses

Togaviruses are positive-sense, single-stranded, enveloped viruses with icosahedral capsids. There are two genera: *Alphavirus* and *Rubivirus*. *Alphavirus* species are arboviruses, whereas *Rubivirus* contains rubella, which is transmitted via droplet or mother-child transmission.

Alphavirus (Equine Encephalitis)

There are three types of equine encephalitis, all belonging to the genus *Alphavirus*, that occur in the Americas and include EEE, Venezuelan equine encephalitis (VEE), and western equine encephalitis (WEE). These viruses affect horses primarily but in 1938 were found to cause human disease in those having close contact with affected animals.

Equine encephalitides are rare human infections and occur either in isolated cases or in short-lived epidemics when environmental conditions favor viral amplification. The WEE and EEE are seen on the coasts of the United States and Canada with some overlap into the Midwest and Great Lakes regions. The VEE occurs throughout Central America into the northern part of South America.

The EEE is the most severe of the equine encephalitides, frequently progressing to coma and death. The disease begins with a short prodrome (~5 d) of a flulike illness: fever, headache, malaise, nausea, and vomiting. This quickly is followed by confusion, stupor or coma, and possibly seizures. Focal neurologic signs can be present, including tremor, cranial nerve palsies, and plegia. In a recent case series, the median CSF white blood cell count was 370 cells/mm^3 (median 70% neutrophils). The median total protein concentration was 97 mg/dL, and the CSF glucose concentration was normal. Diagnosis of EEE encephalitis relies on the detection of IgM antibodies in the serum and/or CSF. The PCR and genomic amplification is available for EEE, and virus isolation from CSF or brain remains the diagnostic gold standard. The majority of those with EEE and neurologic symptoms have abnormal brain MRI. Lesions are best seen on T2-weighted sequences with the basal ganglia and thalamus most affected (Fig. 69.3).

Pathologic findings on gross examination in EEE are similar to other arboviral infections and notable for diffuse cerebral edema. There is typically chronic perivascular and meningeal inflammation seen within the basal ganglia, thalamus, cortex, brainstem, and spinal cord. Lymphocytic infiltrates, microglial nodules, neuronal death, and rarefied white matter can correlate to changes seen on MRI. The EEE immunohistochemistry has shown clusters of infected cells primarily in gray matter, with neurons as the predominant cell type affected (Fig. 69.4). In cases of myelitis, anterior horn cells are affected.

Estimates of case fatalities of EEE range from 30% to 70%. In children, length of prodrome was statistically associated with clinical outcome at the time of discharge, with longer prodromes having more favorable outcomes. This relationship is not as clear

FIGURE 69.3 Axial T2 fluid-attenuated inversion recovery (FLAIR)-weighted magnetic resonance imaging in a patient with encephalitis due to eastern equine encephalitis shows hyperintensities in the basal ganglia bilaterally.

FIGURE 69.4 Histopathologic features in eastern equine encephalitis (EEE). **A:** Hematoxylin and eosin-stained section of thalamus showing perivascular cuffing (*arrow*) (magnification ×20). **B:** Hematoxylin and eosin-stained section showing neuronal degeneration and inflammation. **C:** EEE virus-specific antibody stained section of frontal cortex. (Courtesy of Dr. Pedro Ciarlianì.)

in adults, although patients with more favorable outcomes tended to have longer prodromes. In patients who recover, the morbidity from EEE is high, with sequelae ranging from intellectual disabilities, cranial nerve palsies, hemiplegia, aphasia, and seizures.

The WEE and VEE infections are less severe. The majority have a flulike illness with fever and malaise lasting up to 2 weeks. Risk for neuroinvasive disease includes extremes of age but less than 10% progress to coma. Hemiparesis, tremors, and cranial nerve palsies may occur with long-term sequelae that include cognitive decline and intellectual disabilities.

Rubivirus

Rubella

Rubella, also known as the *German measles*, is caused by a positive-sense, single-stranded RNA virus. The name *rubella* is derived from Latin, meaning "little red," as it generally produces a mild exanthematous disease in children and adults. However, infection occurring during pregnancy, particularly in the first trimester, can result in severe consequences including miscarriage, stillbirth, or infants born with congenital malformations and severe neurologic deficits, known as *congenital rubella syndrome*. Rubella also produces a rare chronic form of progressive encephalitis termed *progressive rubella panencephalitis*, which can be seen in children with congenital rubella syndrome or those with postnatal infections.

In the 1970s, rubella infections occurred in epidemics in the United States approximately every 6 to 9 years prior to licensing of the rubella vaccine. In 2004, after implementation of a universal vaccination program, elimination of endemic rubella virus transmission was documented in the United States. Rubella infections are still prevalent worldwide, as the virus continues to circulate where vaccination programs have not been established. Transmission of the virus is by the respiratory route, and replication occurs in the nasopharynx and lymph nodes.

There can be severe neurologic morbidity from rubella arising when a pregnant woman is infected. The frequency of congenital defects is highest in the first trimester of pregnancy. Infants with congenital rubella syndrome may shed virus from the nasopharynx, eye, or CSF, producing a chronic, persistent infection in the fetus. Neurologic abnormalities are observed by 18 months of age. Infants with rubella encephalitis are hypotonic, inactive, and irritable with a typically full anterior fontanel. Eventually, opisthotonic posturing, rigidity, paresis, seizures, and developmental delays can occur. The syndrome includes sensorineural hearing loss, cardiovascular anomalies, thrombocytopenia, and areas hyperpigmentation about the navel, forehead, and cheeks. In postnatal infections, rubella results in a mild systemic illness with a 2- to 3-week incubation period. Lymphadenopathy is often the initial clue with a subsequent erythematous rash on the face and trunk. The neurologic symptoms are rare, occurring in less than 0.1% of rubella cases. Rubella can produce an encephalitis, meningitis, or myelitis, and there are case reports of GBS following a rash.

Serum abnormalities seen with rubella infections include leukopenia with atypical lymphocytosis or thrombocytopenia. The CSF in postnatal rubella or in congenital rubella syndrome contains a lymphocytic pleocytosis and moderately increased protein concentration. Diagnosis of rubella is supported by detecting rubella-specific IgM and confirmed by detecting rubella virus in throat washings or rubella virus RNA in CSF or urine by using RT-PCR. Rubella virus can be recovered from the CSF of approximately 25% of patients and may persist in the CSF for more than 1 year after birth. On MRI of the brain in congenital rubella syndrome, there are basal ganglia, periventricular and cortical calcifications, multifocal T2 hyperintensities, and evidence of delayed myelination. Pathologically, congenital rubella is characterized by microcephaly, hydrocephalus, and periventricular white matter injury with mineralization (calcification) of the basal ganglia and thalamus.

Prevention is vital in combating rubella. The rubella vaccine is a live attenuated virus typically delivered as part of the MMR (measles, mumps, and rubella) vaccine. Due to risk of congenital rubella syndrome, rubella vaccination is particularly important for nonimmune women who may become pregnant.

Progressive Rubella Panencephalitis

Progressive rubella panencephalitis is an extremely rare and fatal neurodegenerative disorder that can follow either congenital or postnatal rubella infections. Neurologic deterioration following years after a rubella infection was first described in *The New England Journal of Medicine* in two consecutive papers in 1975. Several clinical and neuropathologic features seen in progressive rubella panencephalitis mirror that of subacute sclerosing panencephalitis (SSPE) following measles infections (discussed under "Measles Encephalitis"). Progressive rubella panencephalitis is typically seen in the second decade of life. The syndrome begins with a dementing illness and ataxia, the latter being the

most consistent neurologic sign in progressive rubella panencephalitis. As the disease progresses, the ataxia worsens with dysmetria, dysdiadochokinesia, and truncal titubation. Dysarthria is prominent. The development of pyramidal tract involvement, retinopathy, seizures, and multifocal myoclonus can occur over a protected period of time over 8 to 10 years.

Headache and meningismus are not seen.

Progressive rubella panencephalitis and SSPE occur in people who have elevated antiviral antibodies and apparent intact cellular immunity. In the cases reported of progressive rubella panencephalitis, there were high titers of rubella-specific IgG in CSF and sera. The high ratio of CSF to sera of rubella-specific antibodies suggests intrathecal synthesis. The rubella virus is rarely isolated. In these cases, it is important to rule out the presence of measles-specific antibodies given the similarity in presentations. Electroencephalogram (EEG) reveals diffuse slowing but without the characteristic pattern in SSPE.

Some neuropathologic features of progressive rubella panencephalitis on gross examination include atrophy of the rhombencephalon, centrum semiovale, and basal ganglia with ventricular dilatation, particularly in the fourth ventricle. Microscopically, the cerebellum has atrophy of all cell layers. Neuronal loss is present and widespread. Inclusion bodies seen in SSPE are not present in progressive rubella panencephalitis. There is evidence of chronic inflammation and demyelination with diffuse astrogliosis of the white matter with perivascular lymphocytic and plasma cell infiltrates. Progressive rubella panencephalitis produces a picture similar to vasculitis. There are IgG deposits in cerebral vessels as well as multinucleated giant cells and lymphocytes in vessel walls. Most of the extracted IgG is specific to rubella.

The diagnosis of progressive rubella panencephalitis is easier in children with congenital rubella syndrome. In those who had postnatal rubella infections, the differential should include SSPE as well as dementing illness of childhood. However, with the onset of ataxia, the diagnosis is clearer and demonstration of CSF and sera rubella-specific antibodies is diagnostic. The emphasis remains on preventative measures through vaccination programs, as there are no specific treatments.

CORONAVIRUSES: SEVERE ACUTE RESPIRATORY SYNDROME VIRUS

Epidemiology

The ongoing global pandemic of the novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has had a tremendous impact on global health, resulting in over 19 million cases worldwide with over 700,000 deaths as of August 2020. The SARS-CoV-2 emerged initially from a cluster of pneumonia cases in Wuhan, China, in the end of December 2019. By early January, the China National Institute for Viral Disease Control and Prevention had confirmed the genetic sequence of SARS-CoV-2. By the end of January, WHO declared the coronavirus disease 2019 (COVID-19) outbreak, caused by SARS-CoV-2, a Public Health Emergency of International Concern, and 6 weeks later, WHO characterized the COVID-19 epidemic as a pandemic.

The clinical spectrum of COVID-19 includes respiratory symptoms with approximately 15% to 25% of hospitalized patients developing severe acute respiratory distress and multiorgan damage. Disease severities are associated with older age and underlying comorbidities such as diabetes, hypertension, and cardiovascular disease. While vaccine development is rapidly underway in several clinical trials, the containment of SARS-CoV-2 is currently based on interrupting transmission through rapid identification and isolation of infected individuals. Infection is transmitted primarily through large droplets generated during coughing and sneezing by symptomatic patients but can also occur from asymptomatic individuals.

Human coronaviruses (HCoVs) are a family of large positive-sense single-stranded RNA viruses. The genus is subdivided into four lineages (A-D), with lineage A containing HCoV OC43, HCoV-NL63, HCoV-229E, and HCoV-HKU1; lineage B containing SARS-CoV and SARS-CoV-2; and lineage C containing the Middle East respiratory syndrome-related coronavirus (Fig. 69.5). Data suggests that SARS-CoV, HCoV-229E,

FIGURE 69.5 Schematic of the coronaviridae subfamily depicting the coronaviruses that can infect humans. Abbreviations: HCoV, human coronavirus; MERS-CoV, Middle East respiratory syndrome-related coronavirus; SARS-CoV, severe acute respiratory syndrome coronavirus.

and HCoV-OC43 can infect human neural-cell lines and lead to encephalitis in animal models. These viruses are also detected in CSF, and the SARS-CoV nucleocapsid protein has been identified in the cytoplasm of neurons.

Neurologic Clinical Features Associated With COVID-19

Although the most common manifestations of COVID-19 are respiratory symptoms, extrapulmonary manifestations, including neurologic symptoms and conditions, may also occur. To date, the majority of published cases describing neurologic findings associated with COVID-19 have focused on hospitalized patients. One of the earliest reports of 214 inpatients from three hospitals in Wuhan, China, suggested 36% of adult patients with COVID-19 had neurologic symptoms, including headache, dizziness, confusion, and anosmia. Additional retrospective cohorts from Spain and France reported the prevalence of neurologic symptoms to be 58% and 84%, respectively. At this time, only a few outpatient cohorts detailing neurologic symptoms are available for review. One series suggested that headache was present in 68% and confusion present in 15% out of a total of 248 US outpatients with SARS-CoV-2 PCR-positive tests.

Transient smell and taste disturbances are particularly characteristic of COVID-19 and include anosmia and ageusia. Other neurologic findings include myalgia and rhabdomyolysis, impairment of consciousness, coma, GBS, necrotizing encephalitis, encephalopathy, and myelopathy (Fig. 69.6). Cerebrovascular disease has been a particular concern given evidence of vasculopathy and thrombi in lungs and other organs in COVID-19. As of August 2020, there have been over 100 patients with ischemic or hemorrhagic stroke in the setting of COVID-19 reported in the literature. The majority of reported cases had a history of vascular comorbidities, were older than 60 years, or had a severe systemic illness in the setting of COVID-19. In one US series, large vessel occlusion as a presenting symptom for COVID-19 was reported in five cases in patients younger than 50 years old; prevalence estimates or incidence of stroke in the young during COVID-19 is still unknown. Mechanisms associated with COVID-19–associated strokes include those secondary to sepsis-induced coagulopathy, the production of antiphospholipid antibodies in select cases, and the potential impact of SARS-CoV-2 on brain endothelial and smooth muscle cells. Additional factors include medical comorbidities including hypertension, coronary artery disease, and diabetes seen in those who develop severe COVID-19 infection and the risk of medical complication predisposing to cerebrovascular accidents (ie, atrial arrhythmias, myocardial infarction, myocarditis).

FIGURE 69.6 Neurologic symptoms and diseases associated with COVID-19.

Cerebrospinal Fluid Analyses and Neuroradiographic Imaging in COVID-19

In the majority of COVID-19 cases with lumbar punctures, the CSF cell counts, protein, and glucose were normal; less than 10 publications report elevated opening pressure, CSF leukocytosis, elevated protein, or positive oligoclonal bands in patients with COVID-19. Although the SARS-CoV-2 RT-PCR assay can be run on CSF, the assay has not been validated for clinical use. Most papers report negative CSF SARS-CoV-2 RNA using RT-PCR assays despite patients having abnormal brain imaging or acute neurologic symptoms such as impaired consciousness, stroke, or seizures, or postinfectious syndromes such as GBS. Of the published cases with positive CSF SARS-CoV-2 RNA, three reported elevated CSF leukocytosis or protein, whereas others reported normal cell counts or did not provide details.

Neuroimaging reports have been limited during the pandemic, and reports have focused on MRI in severe or critically ill patients. In several multicenter case series, neuroimaging findings included signal abnormalities in the medial temporal lobe, nonconfluent multifocal subcortical and deep white matter hyperintense lesions on fluid-attenuated inversion recovery, and diffusion with variable enhancement. Extensive and isolated white matter microhemorrhages have also been additionally detected, including punctate hemorrhages in the corpus callosum and subcortical white matter. In one case series, those with hemorrhagic lesions were more likely to be identified in critically ill patients with acute respiratory distress syndrome and pathologic wakefulness once sedation was stopped. The presence of white matter microangiopathy was associated with 2-week poor outcomes. Other MRI features reported include acute necrotizing encephalitis (Fig. 69.7).

Histopathologic Findings Associated With COVID-19

Studies on neuropathologic findings associated with COVID-19 remain a focus of intense interest. In an autopsy series of 18 patients, the primary neuropathologic finding was acute hypoxic injury, with loss of neurons in the cerebral cortex, hippocampus, and cerebellar Purkinje cell layer (Fig. 69.8). There has been limited evidence for diffuse microthrombi or a robust inflammatory response in majority of neuropathologic case series. Thus far, two autopsy series report low copy levels of SARS-CoV-2 RNA in brain tissue, with no definitive evidence of viral protein in a CNS cell; thus, the cellular source of viral RNA in brain tissue remains an open question.

FIGURE 69.7 Magnetic resonance imaging in a patient with acute necrotizing encephalopathy and COVID-19. T2-weighted fluid attenuated inversion recovery scan shows hyperintensity in the bilateral medial temporal lobes and thalami **(A)**. There are hyperintense lesions in thalami and cingulate on diffusion-weighted imaging **(B)** with rim enhancement on gadolinium-enhanced images **(C)** and evidence of hemorrhage on susceptibility-weighted images **(D)**. (Images courtesy Dr. Elissa K. Fory.)

FIGURE 69.8 Histologic findings in patients with COVID-19 illustrating acute hypoxic-ischemic injury with neuronal loss and presence of red neurons in the frontal lobe, hippocampus, and cerebellum; arteriolosclerosis with perivascular rarefaction; a microglial nodule; and perivascular inflammation with scattered microglia (CD45). (Picture from Solomon IH, Normandin E, Bhattacharyya S, et al. Neuropathological features of Covid-19 [published online ahead of print June 12, 2020]. *N Engl J Med*. doi:10.1056/NEJMc2019373.)

ORTHOMYXOVIRUSES: INFLUENZA VIRUS

Influenza is a negative-sense RNA virus with three subtypes (A, B, and C). Further delineation is based on hemagglutinins (H) and neuraminidases (N). The majority of symptomatic infections result in a monophasic, febrile, respiratory illness, but certain hemagglutinin and neuraminidase types confer particularly severe virulence, raising morbidity and mortality.

Neurologic complications are most severe with influenza A and are more commonly seen in children. Additionally, direct CNS infection by influenza is rare, and parainfectious or postinfectious autoimmune and toxin-mediated diseases are more common neurologic complications. Febrile seizures, encephalopathy, Reye syndrome, GBS, and encephalitis have all been described. Influenza-associated encephalopathy typically presents early in the course of the respiratory disease about 1 to 2 days after fever onset. Depressed level of consciousness is invariable. Seizure occurs approximately 80% of the time, and EEG is abnormal. Symptoms can progress to coma and death. The CT and MRI demonstrate focal abnormalities or more widespread edema and are uncommon to have normal neuroimaging in influenza-associated encephalopathy. Treatment for the neurologic complications is aimed at reducing inflammation and edema.

PARAMYXOVIRUSES

Henipaviruses

Hendra virus and Nipah virus are single-stranded, enveloped, negative-sense RNA paramyxoviruses. In the CNS, they cause encephalitis. Their reservoir is the *Pteropus* fruit bat, which resides in Southeast Asia, Madagascar, India, and northern Australia. Outbreaks of Hendra virus have occurred predominantly in Australia, and Nipah virus outbreaks have occurred in Southeast Asia. These are primarily nonhuman viruses: Hendra is an equine virus and Nipah a swine virus, but human transmission has occurred due to both exposure to the fruit bat and exposure to infected animals, usually via saliva. This is extremely rare.

Pathogenesis in the CNS is related both to parenchymal infection and widespread, severe vasculitis. Initial invasion of the CNS seems to occur in a retrograde fashion through the trigeminal nerve or directly across the BBB.

Presentation of Hendra or Nipah virus infection is that of a rapidly progressive encephalitis occurring 1 to 2 weeks after exposure, typically starting as a flulike illness progressing to confusion, seizure, coma, and death over the course of several days. Mortality rate is 40% to 75%, and no definitive treatment exists.

Measles Encephalitis

Measles virus is a small single-stranded RNA virus belonging to the genus *Morbillivirus* of the *Paramyxoviridae* family. Measles virus is highly infectious, spreading rapidly between individuals primarily through aerosolized respiratory droplets over short distances. Measles virus can also be suspended in the air for long periods of time via small-particle aerosols. Infection spread can occur swiftly in a sparsely vaccinated population due to poor herd immunity. The most common manifestation of measles is a febrile childhood exanthem.

Infection with measles virus is associated with a robust cell-mediated immune response and downstream upregulation of cytokines. The virus does not usually replicate extensively in brain tissue, and it is thought that key mutations may be needed to confer a neurovirulent phenotype. Hypothesized viral routes to CNS include migration of infected leukocytes through the BBB, via endothelial cells, or through neuronal viral transport. The virus and subsequent immune response can result in severe brain injury.

There are three main neurologic complications that can arise from measles infections: post–measles encephalomyelitis (PME), measles inclusion body encephalitis (MIBE), and SSPE. The PME is akin to ADEM and is seen weeks after a measles infection. Symptoms include headaches, changes in mental status, and seizures, and most PME cases had preceding morbilliform rash and fever that are typically seen with measles virus. In patients with myelitis, back pain with bladder and bowel dysfunction is prominent. The CSF analysis can show a mild lymphocytic pleocytosis and elevated protein concentrations. The MRI scans demonstrate T2 hyperintensities in the white matter of the brain and spinal cord. In histopathologic studies of the brain, there is evidence of inflammation and demyelination; however, measles virus is not present, suggesting that PME is likely a postviral autoimmune phenomenon.

The MIBE, also known as *immunosuppressive measles encephalitis*, typically occurs months after a measles infection and affects immunocompromised individuals who are unable to clear measles virus. The disease has been described in those with hematologic malignancies, HIV, and solid organ and stem cell transplantation. Nearly all reported MIBE cases have altered mental status and seizures. The seizures are typically refractory focal motor seizures, but generalized seizures and epilepsia partialis continua have been reported. Focal motor deficits, speech impairment, and visual symptoms are also seen. There is progressive deterioration in the level of consciousness typically leading to coma and death in weeks to months. The CSF analysis is usually normal, but a mild pleocytosis and elevated protein concentration may be seen. Brain biopsy is necessary to establish a definitive diagnosis and shows many intranuclear inclusion bodies that contain measles virus nucleocapsids. Measles hemagglutinin and matrix proteins can be visualized by immunohistochemical staining, and intranuclear and intracytoplasmic paramyxovirus particles are seen in neurons, glia, and endothelial cells with electron microscopy. In cases of MIBE and SSPE, it is thought that the virus is likely replication defective making culturing measles virus difficult and the presence of measles is best demonstrated by RT-PCR. The measles vaccine has been implicated as a cause in immunocompromised patients with MIBE.

General supportive measures are the primary treatment. The role of postexposure Ig prophylaxis is unclear. In several patients, intravenous ribavirin treatment has resulted in temporary improvement but is not approved for the treatment. The measles vaccine has been successfully used without serious complications in many immunocompromised patients including those with HIV who do not have evidence of severe immunosuppression. Recent major outbreaks in the United States and abroad have occurred in communicated where groups of people are unvaccinated. Over 1,000 cases of measles have been reported in the United States in the last year alone.

Subacute Sclerosing Panencephalitis

An SSPE is a rare, slowly progressive, fatal disease of the CNS typically occurring in children and young adults. An SSPE develops in immunocompetent persons after a prolonged latent period following a measles infection. There is a higher risk of SSPE associated with a measles infection before the age of 2 years. The disease follows a stereotypic pattern beginning with behavioral changes after a period of weeks to months. Eventually, there is the appearance of myoclonus and focal deficits (speech disorder, ataxia, paresis, or vision loss). If epilepsy is present, generalized tonic-clonic seizures are the most common. As the disease progresses, there is increased pyramidal and extrapyramidal tone and whole-body myoclonic jerks. There have been very few reports of remission; the disease is typically prolonged over months to years and ends in death.

The presence of periodic complexes on EEG is classic for SSPE, with a spike and delta wave component of 0.5- to 3-second duration and intercomplex intervals of 4 to 30 seconds. These complexes are recognizable in the early stages. Those affected with SSPE have elevated levels of measles-specific IgG antibodies in the CSF and serum, unlike in MIBE. There are no specific MRI findings for SSPE. Striking histologic features of SSPE are hypertrophic astrocytes and microglial proliferation. A perivascular infiltration occurs in the cortex and white matter with plasma and other mononuclear cells. Patchy areas of demyelination and gliosis occur in the white matter and deeper layers of the cortex. The neurons of the cortex, basal ganglia, pons, and inferior olives show degenerative changes, sometimes resembling neurofibrillary tangles. Intranuclear inclusions are sparse (see Fig. 69.1D). The measles virus extracted from brain tissue in SSPE is highly defective due to lack of membrane protein production, which renders the virus incapable of being fully assembled and shed from the cell surface.

No drug treatments are available to clear the persistent measles virus from the CNS. Intraventricular interferon with intravenous or intraventricular ribavirin has resulted in clinical improvement or stopped progression in case reports but has not cured the disease. No controlled studies have been performed for SSPE. The focus remains on symptomatic and supportive treatments including treatment of myoclonus and seizures, but the disease and its sequelae are entirely preventable by maintaining measles immunization rates greater than 90% in populations.

RHABDOVIRUS: RABIES

Rabies is one of the most deadly and feared viruses with fatality rates essentially at 100%. The disease is present in all continents, except in Antarctica, with the predominant burden of illness in Asia and Africa. It has a variable incubation period followed by pain or paresthesia at the site of the bite and ultimately a progressive encephalomyelitis and death.

Epidemiology

Rabies is underreported in many areas around the world with estimated worldwide mortality of approximately 59,000 per year and remains one of the deadliest viruses on the plant. The typical route of transmission is via the bite of an infected animal, allowing breakdown of the dermal barrier and deposition of the virus into tissues. Although rabid dogs remain the principle vector for human rabies and is the cause of >95% of human rabies death worldwide, bat-acquired rabies is becoming increasingly common, especially in regions where rabies is controlled via vaccination programs in dogs and other carnivores. During 1960-2018, there were 89 US acquired cases of human rabies, 62 (70%) were attributed to bats. Dog bites acquired during international travel were the cause of 26 cases. Humans are considered dead-end hosts, with human-to-human transmissions occurring only in rare circumstances, such as in transplantations. Airborne transmission of rabies has been reported in spelunkers of bat-infested caves and laboratory workers with no known bat bites.

Pathobiology

Rabies is derived from a negative-sense, single-stranded RNA virus belonging to the genus *Lyssavirus*. The virus is enveloped and bacilliform (bullet-shaped). Once transcribed by the host, viral replication and transcription occur in cytoplasmic inclusions within neuronal cells termed *Negri bodies*. The virus then is able to use the host cell machinery to travel retrograde by axonal transport mechanisms to the dorsal root ganglia or cell bodies in the spinal cord or brainstem. In the CNS, viral replication is enhanced and clinical disease develops.

Clinical Features

There are two clinical forms of rabies described, encephalitic and paralytic, and presentations may depend on transmission type (eg bat vs dog bite). The earliest symptom reported is pain or paresthesia at the site of infection in about half of patients due to viral replication in the local dorsal root ganglia. Other symptoms include fever, headache, and lethargy. The encephalitic course is heralded by hypersalivation, alternating patterns of agitation and lucidity, and hydrophobia leading to pharyngeal spasms, all ultimately leading to coma and death. The paralytic form classically begins with limb weakness early; there are no convulsions or laryngeal spasms. The paralysis results in flaccid tone and can spread to involve other limbs. The paralytic form of rabies has a longer prodromal period and a more protracted course. The typical incubation period is 1 to 6 months. Longer incubations (including a case 8 y postexposure) have been reported.

Diagnosis

Diagnostic tests rely on the widespread dissemination of the virus. An MRI of the affected brain shows a pattern of mild T2 hyperintensities primarily in the brainstem, hippocampus, thalamus, and cerebral white matter (Fig. 69.9). Postcontrast enhancement in the brain is observed late in the course. In paralytic rabies, the brachial plexus can enhance in the prodromal phase. The MRI changes seen in rabies are preferential to the brainstem.

The diagnosis can be made by fluorescent antibody staining of corneal smears or nuchal skin biopsies, although both false-negative and false-positive results occur, and/or by the detection of viral nucleic acid using RT-PCR in biologic fluids including saliva and CSF. Although viral shedding in saliva is used for testing, sensitivity on single sample testing can be as low as 70%. This is attributed to intermittent shedding, and thus, multiple successive saliva samples or skin biopsies reach sensitivities greater than 95%.

FIGURE 69.9 **A:** Axial diffusion-weighted imaging **(far left)**, apparent diffusion coefficient **(middle)**, and T1-weighted magnetic resonance imaging after administration of gadolinium **(right)** at the level of the caudate heads in a patient with rabies encephalitis demonstrate diffusion restriction within the subcortical white matter *(arrows)* and diffuse leptomeningeal enhancement *(arrowheads)*. The white matter diffusion restriction is thought secondary to wallerian degeneration and leptomeningeal enhancement to leptomeningitis. **B:** Hematoxylin and eosin-stained section of neurons within the spinal cord shows the characteristic sharply defined eosinophilic inclusion called *Negri body* in a patient with rabies encephalitis.

Histopathologic diagnosis of rabies was for many years dependent on visualization of Negri bodies in infected neurons on biopsies. These are cytoplasmic inclusions, which are classically round or ovoid eosinophilic bodies. Negri bodies are most prominent in the brainstem, hippocampus, and in Purkinje cells but can been seen in cortical neurons and spinal ganglia. A histologic picture of gray matter-centric encephalitis and/or myelitis can occur but is not universal, as considerable variability in the inflammatory response may be due to differences in the infecting rabies virus strain. Rabies viral antigen is frequently identified in cases where Negri bodies are absent and can be shown in non-CNS tissue including the cornea and nasal mucosa.

Treatment

No effective therapies exist for rabies after the development of symptoms. Of the individuals who have survived, one received preexposure immunization and eight received postexposure prophylaxis prior to the onset of symptoms. There has been a single case of a 15-year-old girl who was in contact with a bat 1 month prior to symptom onset and did not receive postexposure prophylaxis who survived after treatment with a combination of medical therapies, which included therapeutic coma with ribavirin, amantadine, benzodiazepines, and ketamine, dubbed the "Milwaukee protocol." This paradigm with case-by-case modifications for the treatment of rabies remains controversial, as at least 26 subsequent cases have failed to repeat this isolated success. Additional therapies for rabies, including Ig plus vaccination, ribavirin, and interferon α, have not been successful to date. Thus, the best approach to rabies is exposure avoidance and vaccinating those anticipating potential exposure. Access to postexposure prophylaxis may be lifesaving for those who do become exposed.

ARENAVIRUSES

Arenaviruses are present throughout the world and infect mammalian, largely rodent, species and reptiles endemic to their respective geographic region. Currently, there are 41 distinct viral species recognized in the genus *Mammarenavirus* that encompasses virus that infect mammals. These are negative-sense single-stranded RNA viruses. "Old world" arenaviruses include Lassa and Luho virus, largely confined to the African continent, and lymphocytic choriomeningitis virus (LCMV), which has a global distribution via its *Mus musculus* host. "New world" arenaviruses include Whitewater Arroyo virus in North America, Junin virus in Argentina, and Machupo virus in Bolivia and parts of Paraguay. Recent surveillance indicates there are novel arenavirus strains circulating in Asia, which are phylogenetically similar to "old world" arenaviruses, and some strains have the capacity to cause human infection.

In rodent hosts, a typically nonpathogenic chronic viremia can result in transmission to humans via direct contact that includes animal bites or through inhalation of infectious urine and feces. The LCMV causes neurologic diseases further described in the following section. Lassa, Whitewater Arroyo virus, Junin, and Machupo all cause hemorrhagic fever, with mortality rates of 15% to 35%. Symptoms start as a febrile illness that can progress to encephalopathy and severe thrombocytopenia and platelet aggregation inhibition, resulting in multifocal hemorrhage. These infections tend to occur in outbreaks, and men are more frequently affected than women, a feature potentially related to exposure patterns.

Lymphocytic Choriomeningitis Virus

A common mode of LCMV infection is via exposure to infected rodents and is typically asymptomatic when the host is immune competent. Although LCMV is common in the house mouse, LCMV outbreaks in humans have also been linked to pet hamsters. Reported outbreaks in the setting of solid organ transplantation occur rarely, but with uniformly fatal outcomes. Many solid organ donors in whom the transplant recipients died from LCMV infection were unaware of being infected. Vertical transmission can also occur.

Clinical Manifestations

In humans, LCMV incubation time is typically 1 to 2 weeks followed by fevers, chill, and general malaise. The LCMV is neurotropic, and viremia can result in carriage of virus to brain. The most common neurologic complication is self-limited viral meningitis, eponymously known as *Wallgren syndrome*; encephalitis is rare, although in a study of undiagnosed encephalitis, 2.3% individuals had LCMV infection, suggesting the infection may

be underdiagnosed. There are cases of LCMV infection associated with acute hydrocephalus. Other complications include orchitis, arthritis, pericarditis, pancreatitis, and cutaneous rash.

Diagnosis and Treatment

Although CSF studies in the immunocompromised may be acellular, in immune competent hosts, moderate to striking lymphocytic pleocytosis can occur (exceeding 1,000 cells/μL) in addition to elevated protein concentrations and hypoglycorrhachia. Pleocytosis can persist for over 1 month, an unusual feature in viral meningitis. The LCMV RNA can occasionally be detected in blood or CSF, but diagnosis is more reliably made by serology. To our knowledge, there are no current trials of antiviral agents in human LCMV disease, and treatment remains supportive (level III: expert opinion).

The LCMV is also an important teratogen, and reported cases are largely described in the United States. About half of the mothers had symptomatic infections, and one-third had rodent exposures, which suggests an education potential for prevention purposes. Children born to these mothers suffered chorioretinitis, hydrocephalus, and/or periventricular calcifications.

Adenovirus

Adenovirus is a nonenveloped, double-stranded DNA virus with an icosahedral capsid belonging to the *Adenoviridae* family. Infection primarily occurs in mucoepithelial cells of the respiratory tract, conjunctiva, and gastrointestinal tracts, followed by lymphoid tissue replication and subsequent viremia. Infections can be monophasic, but the virus can alternatively establish latency and oncologic transformation.

Adenovirus infection of the nervous system in immunocompetent adults is rare and described in case reports. In at least four large, prospective cohorts identifying clinical causes for encephalitis with approximately 1,000 individuals, most adults, none were attributed to adenovirus. Neurologic symptoms, including seizures, encephalitis, and visual hallucinations in the setting of adenovirus infection, has been reported in 3% to 5% of infected children in cohort studies; most cases do have adenovirus detected in the CSF but detected in the respiratory or gastrointestinal tract. Adenovirus infection in adults typically occurs in the setting of primary or secondary immunodeficiency and can be devastating in when disseminated. Meningoencephalitis may progress to involve the spinal cord resulting in myelitis with other features that include headache, fever, stupor, and coma. The CSF may show elevated protein concentration and detectable adenovirus DNA. Adenovirus has tropism for ependymal cells resulting in its inflammation; other viruses that have tropism for the ependyma include CMV and mumps virus. The MRI abnormalities are nonspecific with T2 hyperintense signal in temporal lobes, bilateral limbic systems, brainstem, and cerebellum along with mild patchy enhancement, mass effect, and hemorrhage in some cases.

Pathology demonstrates widespread gliosis, neuronal loss, lymphocytic infiltrates, microglial nodules, necrosis, and adenoviral neuronal inclusions most prominent in the brainstem and diencephalon, with the posterior horns predominantly affected in myelitis (**Fig. 69.10**). Although limited epidemiologic data on outcomes exist, reported outcomes are poor in immunosuppressed individuals with adenoviral meningoencephalitis. Observational case series have supported limited efficacy for cidofovir and riboviran in the treatment of adenovirus infections in immunocompromised hosts, but no controlled trials determining efficacy of these agents in adenoviral meningoencephalitis are available (optional, level III: expert opinion). Brincidofovir is an investigational orally administered conjugate of cidofovir developed for the treatment of adenovirus infection, although its efficacy for CNS infection is unknown (**Table 69.2**).

FIGURE 69.10 Neuropathology of adenovirus encephalitis. **A:** Hematoxylin and eosin-stained section of the cerebellar dentate nucleus shows two prominent microglial nodule with associated lymphocytic infiltrates. **B:** Hematoxylin and eosin-stained section of the basal ganglia shows the perivascular nature of lymphocytic infiltrates. **C:** Hematoxylin and eosin-stained section of the choroid plexus of the lateral ventricle shows inflammation present within the structures of the choroid plexus, which leads to ventriculitis. **D:** Electron microscopy image shows multiple icosahedral viral particles within the nuclei of a neuron, consistent with adenovirus.

TABLE 69.2 Antiviral Agents for Prophylaxis and Treatment of Herpes Central Nervous System Disease[a]

Antiviral Agents for Treatment of CNS Disease	HSV	VZV	CMV	EBV	HHV-6
Commercially Available					
Acyclovir (IV)	x	x			
Ganciclovir (IV)		Alternative	x + foscarnet[b]		x[c]
Foscarnet (IV)			x + ganciclovir[b]		x
Cidofovir (IV)			Second-line agent[d]		Second-line agent
Activity of Antiviral Agents Used in Prophylaxis	**HSV**	**VZV**	**CMV**	**EBV**	**HHV-6**
Commercially Available					
Acyclovir/valacyclovir/famciclovir[e]	x	x	High dose +/−		
Ganciclovir (IV)/valganciclovir (orally)	x	x	x		x
Letermovir			x		x
Novel/Investigational Antiviral Agents					
Brincidofovir (cidofovir prodrug)[f]	x	x	x	x	x
Maribavir[g]	x			x	

Abbreviations: CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein-Barr virus; HHV-6, human herpesvirus 6; HSV, herpes simplex virus; IV, intravenous; VZV, varicella-zoster virus.
[a]Prophylaxis table courtesy of Dr. Camille Kotton, MGH.
[b]Dual therapy in cases of severe CNS disease (eg, encephalitis); monotherapy can be considered if unable to tolerated dual therapy or in mild disease (eg, CMV mononeuritis multiplex with mild motor deficits).
[c]Ganciclovir may not be active against HHV-6A due to resistance.
[d]Cidofovir is alternative in patients who are unable to tolerate other options; no trial data for CNS neurologic disease, evidence for use in CMV retinitis.
[e]Specifically in prophylaxis.
[f]Outside of CMV, no clinical data on therapeutic efficacy with other herpes viruses; primarily in vitro studies.
[g]Primarily in vitro data.
Note: x indicates therapeutic efficacy.

HERPESVIRUSES

Human herpesviruses are neurotropic viruses that establish latent infections within the nervous system for the lifetime of their host. These viruses contain double-stranded DNA molecules and consist of eight members: herpes simplex virus 1 and 2 (HSV-1, HSV-2); VZV; CMV; EBV; and human herpesvirus 6, 7, and 8 (HHV-6, HHV-7, HHV-8, respectively). These are pleiotropic viruses capable of tissue injury, vasculitis, angiogenesis, and tumorigenesis. Antiviral therapeutics for herpes viruses are shown in Table 69.2.

Herpes Simplex Virus 1 and 2

The HSV-1 and HSV-2 share 70% genomic homology, and both establish latent infections in dorsal root ganglia. These viruses can reactivate years later and cause meningitis (HSV-2 predominantly) or encephalitis (HSV-1 primarily). In adults, seroprevalence for HSV-1 and HSV-2 is 50% to 90% and 4% to 40%, respectively.

Herpes Simplex Virus Encephalitis

The HSE is the most common cause of encephalitis in immunocompetent people in the United States, Europe, and Australia. Two to three cases per million population per year occur with peak incidence in the 60s. Most commonly, infection is associated with HSV-1, although HSV-2 can be responsible for HSE in immunosuppressed individuals or in neonates. The pathogenesis for HSE involves reactivation within the trigeminal ganglion with axonal spread into the frontal and temporal lobes, CNS reactivation, and/or primary infection of the CNS.

Clinical Manifestations

Clinical presentations represent symptoms associated with temporal lobe involvement and include headache and fever, with personality or behavioral changes, disorientation, and/or seizures. The combination of fever and headache with personality changes or confusion is seen in the majority of cases, although only rarely will an individual have the complete triad of symptoms (Fig. 69.11).

Diagnosis

The CSF is abnormal in more than 95% of HSE patients, revealing a moderate pleocytosis with predominately mononuclear cells. Red blood cells are frequently present. There can be a moderate increase in CSF protein concentration, whereas hypoglycorrhachia is seen only occasionally and not expected. The PCR for HSV-1 is 98% sensitive and 94% specific. False-negative results can be seen during the first 72 hours of illness, and testing can turn positive 1 to 2 days later. The PCR results can remain positive even while on treatment in 40% of HSE patients, although by and large, these statistics do not come from therapy with acyclovir. The CSF white blood cell count in immunocompromised hosts may not be elevated, and in general, immunocompromised patients have lower white blood cell count numbers in comparison to those with healthy immune systems. The EEG changes are nonspecific and classically demonstrate periodic lateralized epileptiform discharges or seizures. The MRI is the superior imaging modality, demonstrating abnormalities 24 to 48 hours earlier than CT. The diagnosis of HSE is supported by T2 hyperintensities in cortical and subcortical regions of the medial temporal lobes, insula, orbitofrontal, and cingulate gyri (see Fig. 69.11A).

A B

FIGURE 69.11 A: Axial T2-weighted fluid-attenuated inversion recovery magnetic resonance imaging at the level of the superior cerebellar peduncle and tentorium cerebelli in a patient with limbic encephalitis due to herpes simplex virus 1 demonstrates T2 hyperintensity and edema in the anterior temporal lobe on the right. B: Macroscopic view of the base of the brain after fixation shows hemorrhagic necrosis of the left temporal lobe and cavitated necrosis of the right temporal lobe in this case of herpetic encephalitis.

There may be additional evidence of subacute hemorrhages within edematous brain tissue. Restricted diffusion correlates with cytotoxic edema and is present early in disease. Because the clinical and radiologic features together with CSF analysis are typically sufficient for diagnosis, pathologic evaluation is seldom needed. Characteristic neuropathologic changes of herpetic encephalitis include extensive necrotizing involvement of the temporal lobes with associated hemorrhage (see Fig. 69.11B), and microscopically abundant inflammatory infiltrates dominated by macrophages and lymphocytes, with limited evidence of viral cytopathic changes. In the chronic phase, the lesions evolve into cavitary spaces with surrounding gliosis. The presence of HSV-1/HSV-2 particles can be confirmed by immunohistochemistry or electron microscopy.

Treatment

The introduction of acyclovir in 1984, which prevents viral replication by DNA polymerase inhibition, resulted in dramatically reduced mortality rates from HSE. Acyclovir for HSE is dosed at 10 mg/kg every 8 hours for 21 days in patients with normal renal function LEVEL 2[1,2]; relapse is an issue in undertreated patients. If the patient is not clinically improving, foscarnet can be substituted for acyclovir.

Resistance to acyclovir is uncommon in patients who have not received treatment in the past. Acyclovir resistance stems from viral thymidine kinase mutations in 95% of cases or in viral DNA polymerase genes. In immunocompromised patients receiving long-term prophylactic acyclovir, the risk of acyclovir-resistant HSV and VZV increases, and treatment with foscarnet and cidofovir are considered second-line agents (expert opinion).

Outcome

The HSE is a medical emergency, as prognosis is dependent on early initiation of treatment. Despite highly favorable results with acyclovir, treatment initiation continues to be delayed primarily due to failure to recognize the disease early, and predictors of adverse outcomes despite treatment include age (older than 30 y old), Glasgow Coma Scale score less than 6, and duration of symptoms prior to starting acyclovir. The HSE can trigger an autoimmune encephalitis in 5% to 27% of cases with neurologic deterioration similar in clinical features to HSE reactivation. The development of antibodies targeting neuronal antigens (*N*-methyl-D-aspartate receptor or other antibodies) proceeded clinical symptoms and occurs on average 2 months after initial infection. Based on case series and expert opinion publications, treatment for autoimmune encephalitis post-HSE infection can include steroids, IVIG, and other immunomodulatory therapies once HSV infection is confirmed to be negative.

Neonatal Herpes Simplex Virus 2 Encephalitis

Neonatal HSV infections are life-threatening infections in newborns. In the United States, neonatal HSV encephalitis affects approximately 1,500 to 2,220 babies per year, and HSV-2 accounts for 70% of these cases. The HSV infections in infants are grouped into three categories: disseminated disease; CNS involvement; and limited disease to the skin, eyes, and/or mouth, and classification is predictive of morbidity and mortality. Factors influencing outcomes in neonatal HSE include prematurity, seizures, and multiple dermatologic infections of the skin. The clinical manifestations include nonspecific signs of encephalitis/meningitis such as lethargy, poor feeding, labile temperature, seizures, opisthotonus, and bulging fontanels. The median age of presentation for HSV-2 encephalitis is day 16 to 19 of life. Pathologically, as opposed to typical herpetic encephalitis, the necrotizing lesions do not show a preference for specific brain regions, and nuclear viral inclusions are more frequent due to an overall high viral burden.

Neonatal CSF HSV PCR is highly sensitive and specific for herpes DNA. The HSV DNA is detectable in the first week of illness even while on antiviral therapy. Initiation of acyclovir should ideally occur before the development of CNS disease, disseminated disease, or depressed consciousness as this has been shown to improve outcomes. The first-line treatment for neonatal HSE is intravenous acyclovir at 60 mg/kg/d divided three times a day for 21 days LEVEL 2.[3] It is recommended to obtain a repeat CSF HSV PCR at the end of therapy and, if HSV DNA is still present, to continue therapy. There is higher morbidity and mortality associated with prolonged HSV infection despite therapy. Mortality in the era of antiviral therapy is 4% for CNS HSV disease at 1 year. Long-term neurologic consequences include cerebral palsy, intellectual disabilities, attention deficits, and epilepsy.

Benign Recurrent Lymphocytic Meningitis

A syndrome of recurrent episodes of benign, self-limited, sterile meningitis were first described by Mollaret in 1944. For years, the condition was referred to as *Mollaret meningitis*.

Pathobiology

Benign recurrent lymphocytic meningitis has been associated with herpes virus infections. In recent years, detection of HSV-2 genome by PCR has been most often, but not uniformly, reported.

Other cases have been linked to varicella-zoster infection. The CNS epidermoid cysts can give rise to Mollaret meningitis especially with surgical manipulation of cyst contents. A familial association, where more than one family member had Mollaret, has been documented. Recently, evidence has shown that some patients develop autoimmune encephalitis after HSV encephalitis, particularly in children. These patients may respond to immunomodulatory treatment.

Clinical Manifestations

The syndrome is characterized by recurrent and spontaneously remitting attacks of headache and nuchal rigidity, usually recurring for 3 to 5 years. Meningitis usually last 2 or 3 days and typically mild without associated neurologic abnormalities. The initial attack can occur anytime between childhood and late adult years, and both genders are equally affected.

Diagnosis

The CSF pleocytosis, mild elevation of protein concentration, and normal glucose is typical during attacks. The cell count ranges from 200 to several thousand cells per cubic millimeter; most cells are mononuclear. Although large endothelial cells are found in the CSF in the early phases, their presence is variable and not required for diagnosis.

Diagnosis and Treatment

Patients with Mollaret meningitis recover rapidly and spontaneously without specific therapy. There is no effective therapy for shortening the attack or preventing attacks. In anecdotal reports, acyclovir was beneficial (level III).

Varicella-Zoster Virus

The VZV is a human herpesvirus that causes both a primary infection (chickenpox) and can reactivate, producing shingles (zoster), meningitis, vasculitis, and encephalitis. After primary infection, the virus persists in a latent form within cranial nerve or dorsal root ganglia and has periods of reactivation and shedding. A VZV reactivation primarily occurs from the spinal ganglia, with the thorax being the most common site of latent infection, followed by lumbar, cervical, and then sacral regions. A VZV encephalitis is more common in those with immunodeficiency or immunosenescence (waning T-cell immunity to varicella). Neurologic complications can occur without prodromal symptoms including rash. Diagnosis is confirmed with either VZV DNA or anti-VZV IgM detection in the CSF. Intravenous acyclovir 10 to 15 mg/kg every 8 hours for 10 to 14 days is the recommended treatment, with oral prophylaxis prescribed afterward.

Herpes Zoster

Herpes zoster primarily is seen in those older than age 50 years and in immunocompromised people, particularly those with HIV or transplant recipients. Over 30% of the population will have herpes zoster at some point in their life. There is an age-specific rise in incidence rates in those older than age 80 years to 8 to 12 per 1,000 person-years. It is estimated the number of zoster infections worldwide is rising because the general population is aging, the availability of antiviral treatment has had the effect of more people being diagnosed, and those who are immunocompromised are living longer.

Pain typically heralds the onset of zoster. The pain of zoster is described as severe, sharp, radicular pain in the distribution of the affected nerve root. The pain can be associated with pruritus and paresthesia. A unilateral dermatomal vesicular rash in the area supplied by the affected root or roots typically follows days later. The vesicles are usually clustered and contain clear fluid, which then desquamate and scab within 5 to 10 days. Occasionally, the pain is present without the ensuing rash in a condition known as *zoster sine herpete*. Treatment choices for uncomplicated zoster include oral acyclovir, valacyclovir, or famciclovir with preferential use of valacyclovir or famciclovir due to similar dosing and better CNS pharmacokinetics. A 7- to 10-day course of antiviral therapy is recommended LEVEL 1.[4]

Cranial ganglia are affected in approximately 20% of people. In those with cranial nerve involvement, the trigeminal nerve is most often affected. Zoster ophthalmicus, within the cranial nerve V1 distribution of the trigeminal nerve, is often accompanied by keratitis and can lead to blindness. A vesicular rash at the tip of the nose (Hutchinson sign) is a strong predictor of ocular involvement, indicating involvement of the nasociliary branch of V1, which also supplies the cornea and conjunctiva. A herpes zoster rash can precede optic neuritis or ophthalmoplegia. The combination of facial palsy and vesicles in the external auditory canal, tympanic membrane, or on the ipsilateral anterior tongue or hard palate is termed *Ramsay Hunt syndrome*. This syndrome is an indicator of zoster involvement of the facial nerve. The facial palsy in Ramsay Hunt syndrome can be severe, and those affected are less likely to recover.

A common complication of zoster is the development of postherpetic neuralgia (PHN), occurring in at least one-third of people affected by shingles. The definition of PHN varies but is generally defined as continued pain in the affected dermatome that persists beyond 4 to 6 weeks after resolution of a rash. The risk of developing PHN varies and is highest in the elderly as well as those who are immunocompromised. Several prospective studies report that 30% to 50% of patients with PHN experience pain lasting over 1 year and with some experiencing pain lasting up to 10 years. The central mechanisms for PHN remain unknown. Treatment of PHN is difficult, and pain can be refractory to multiple analgesics. Combinations of topical treatments (lidocaine or capsaicin) and oral analgesics (tricyclic antidepressants, anticonvulsants, and opioids) are typically used. Interventions such as sympathetic nerve blocks, epidural injections of lidocaine or steroids, or pulsed radiofrequencies have either failed to demonstrate benefit or the data is not robust to recommend these procedures.

A VZV infection can rarely result in muscle weakness affecting bulbar, limb, or truncal muscles and is typically within the distribution predicted by the rash. For example, peripheral facial weakness is seen with VZV oticus or unilateral diaphragmatic paresis when affecting the cervical myotomes. Sacral herpes zoster can result in neurogenic bladder and loss of anal sphincter control. Segmental zoster paresis is highly associated with PHN. In patients with postganglionic lesions, an MRI can show T2 signal hyperintensity within the affected plexus or nerve, enlargement of the nerve, or enhancement.

Symptomatic ataxia can occur with primary varicella infections and is traditionally seen in children. Acute cerebellar ataxia is due to either direct viral infection of the cerebellum or is a parainfectious process. Ataxia can be antecedent to or present up to 14 days after the onset of a primary varicella rash. Those with varicella-related acute cerebellar ataxia tend to have worse ataxia than seen in other viral syndromes but have more rapid rates of recovery with good neurologic outcomes (Fig. 69.12).

FIGURE 69.12 Midsagittal T2-weighted **(far left)** and postcontrast T1-weighted **(middle)** images of the thoracic spine from a patient with varicella-zoster myelopathy show multiple levels of intrinsic cord T2 hyperintensity **(left)** with patchy enhancement **(middle)** from T10 to T12 *(arrow)*; axial T2-weighted image **(right)** at the level of T12 demonstrates both white and gray matter involvement by the lesion.

Additionally, the VZV is emerging as a relevant ischemic and hemorrhagic stroke risk factor. Large population studies in the United Kingdom and Taiwan show an increase in the incidence of stroke or transient ischemic attack the year following herpes zoster, with a greater relative risk (4.5-fold higher) after herpes zoster ophthalmicus. In pediatric populations, nearly one-third of ischemic arteriopathies are associated with varicella infections.

The hypothesis is that reactivation from ganglia results in viral spread to the adventitia of local blood vessels and eventual transmural migration into the media. The VZV is the only virus known to replicate within arterial vessels. Inflammatory cells including neutrophils in early VZV vasculopathy and T cells are directed to the infected sites secreting inflammatory factors that result in remodeling of the vessel. Pathology demonstrates lymphocytes and multinucleated giant cells, intranuclear viral inclusion bodies, and viral particles in endothelial and vessel wall cells within arteries. The VZV vasculopathy affects small and large arteries with an emphasis on small artery involvement. In contrast, immunocompromised hosts can develop the entire spectrum of small, large, and mixed artery involvement with VZV vasculopathy.

Those affected with VZV vasculopathy do not necessarily have a history of zoster or varicella rash. In cases when a zoster rash is present, there was often a time delay of an average of 4 months between the rash and neurologic symptoms. Anti-VZV IgM in the CSF is more sensitive than CSF VZV DNA for detecting VZV-associated vasculopathy. When VZV vasculopathy is suspected or confirmed, treatment with intravenous acyclovir for a minimum of 14 days is suggested based on category 3 evidence (expert opinion). Oral prednisone at 1 mg/kg for 5 days without taper has been given as an adjuvant to suppress the inflammatory response in arteries, but this dosing is arbitrary.

Myelitis may complicate acute varicella infection or can be a consequence of reactivation. Clinical features include paraparesis with a sensory level approximately 1 to 2 weeks following a dermatomal rash. The T2-weighted MRIs can show focal areas of hyperintense lesions (see Fig. 69.9). Immunocompromised hosts have a more progressive, insidious course that can be ultimately fatal. Histopathology shows areas of necrosis and inflammation with involvement of the spinal cord by VZV. Diagnosis is confirmed by presence of VZV DNA and/or anti-VZV IgM in the CSF. Aggressive treatment with intravenous acyclovir and consideration of corticosteroids may produce a favorable response, although evidence is lacking.

Prevention

To date, there are two vaccines for the prevention of herpes zoster, Zostavax and Shingrix, available in the United States. Zostavax is a live attenuated vaccine that was approved in 2006, whereas Shingrix is an adjuvanted recombinant subunit vaccine that was approved in 2017. A large phase 3 trial for the Shingrix vaccine was performed in 14,759 immunocompetent patients 50 years or older who had not had a previous history of herpes zoster or had an immunosuppressive condition. This trial showed effectiveness in reducing the rate of herpes zoster in vaccinated adults compared to placebo. Current CDC guidelines recommend Shingrix vaccination in immunocompetent adults ages 50 years and older, irrespective if they had a prior episode of shingles or received the Zostavax vaccination, and individuals with chronic medical conditions, those on low-dose immunosuppressive medications or anticipating immunosuppression.

Epstein-Barr Virus

The EBV is a double-stranded, helical DNA gamma herpesvirus that infects B lymphocytes primarily and subsequently establishes latency. In the nervous system, primary infection is associated with meningitis, encephalitis, myelitis, radiculitis, cerebellar ataxia, GBS, and ADEM. These entities and associations are rare. The CNS disease due to reactivation is primarily seen in the setting of profound immune suppression, whereby primary CNS lymphoma is precipitated by EBV-mediated B-cell transformation; this is most closely associated with advanced HIV infection. However, there are case reports of meningoencephalomyelitis occurring in the setting of apparent reactivation.

The EBV is one of the most common infections worldwide. Primary inoculation occurs usually by adolescence through infected saliva transfer. The virus replicates in the pharyngeal tonsils and transforms short-lived B lymphocytes to prevent their apoptosis. Primary infection is usually asymptomatic, but infectious mononucleosis can also occur about a month into infection. This is characterized by profound fatigue, lymphadenopathy, splenomegaly, and fever. The nervous system complications mentioned earlier rarely follow. In ADEM or GBS, pathophysiology is due to parainfectious inflammation. For the other entities, there is at least a component of inflammation, and the degree of direct viral pathogenesis is unknown but likely small if any.

Diagnosis of primary EBV infection is by serology. The detection of viral capsid antigen IgM indicates recent infection; in chronic/latent infection, this antibody wanes in favor of viral capsid antigen IgG and EBV nuclear antigen. The EBV DNA can be detected in blood and CSF as well, but this does not indicate pathogenic connection to the disease. Treatment is supportive aside from EBV-associated primary CNS lymphoma, which is treated as a neoplasm with chemotherapy and/or radiation. In the setting of primary infection nervous system complications, treatment often involves corticosteroids, IVIG, and/or plasmapheresis.

Pathologic studies of CNS EBV infections unrelated to primary CNS lymphoma are lacking. Although the virus is detectable in CSF, its positive predictive value is low. Furthermore, replication can occur in the setting of other infections or illnesses, which makes caution in interpreting results of paramount importance, as this finding could very well be an epiphenomenon. In AIDS-related disease, detection of EBV DNA from CSF has a high sensitivity and specificity for CNS lymphoma.

Cytomegalovirus

The CMV is a common cause of viral opportunistic infections in persons who are immunocompromised from either HIV (CD4 counts <50 cells/mm^3) or those who have undergone transplantation. The CMV is also the most common cause of congenital viral infection resulting in neurologic impairments. In the general population, CMV seroprevalence varies considerably, ranging from 50% to 80% in sexually active adults. Symptomatic CMV infections of the nervous system in adults can result in retinitis, encephalitis, polyradiculitis (usually of the lumbosacral nerve roots), myelitis, or vasculitic mononeuritis multiplex. Since the advent of antiretroviral therapy (ART), the incidence of CMV infections affecting the CNS has decreased.

Clinical Manifestations

The CMV encephalitis clinically presents as a subacute encephalopathy with features of disorientation, lethargy, apathy, and possibly fever. Focal neurologic deficits include seizures and cranial nerve palsies. Clinical signs of brainstem or cerebellar involvement occur in about 30% of those affected. Additionally, CMV can produce a lumbosacral polyradiculopathy that is often associated with concurrent infection elsewhere. Those with polyradiculopathy develop subacute lower extremity weakness, paresthesia, and lumbar pain with progression to flaccid paraplegia and areflexia. Ascending sensory loss is often asymmetric. Sacral involvement includes urinary retention and fecal incontinence. If perianal anesthesia is present, there is likely anal sphincter dysfunction and conus medullaris involvement, similar to Elsberg syndrome most commonly seen in the setting of HSV-2 reactivation.

Although congenital CMV infections are mainly asymptomatic, 10% to 15% of infants will develop symptoms. The incidence varies in different populations around the world with rates ranging from 0.2% to 3% of all births. Vertical CMV transmission can result from primary maternal infection in pregnancy, can follow reactivation of a previous infection, or can be seen by reinfection with a new strain. Long-term sequelae include sensorineural hearing loss, microcephaly, chorioretinitis and/or optic atrophy, seizures, and a wide range of intellectual developmental disorders.

Diagnosis and Treatment

The MRI of the brain can show periventricular enhancement or increased T2 hyperintensity on the ependymal surfaces or can be entirely normal. A CSF pleocytosis is rare, and if present, it is a mild lymphocytic pleocytosis with an elevation in CSF protein concentration. The diagnosis in the correct clinical setting is strongly supported by a positive CSF CMV PCR (sensitivity 60%-100%; specificity 89%-100%). Although there are different histologic patterns of cytomegaloviral congenital encephalitis typical findings include inflammatory infiltrates with lymphocytes, microglial nodules, necrosis, ventriculitis, and typical intranuclear darkly eosinophilic cytomegalic inclusions in infected cells (which may be neurons, glia, and endothelial cells). If inclusions are difficult to identify, immunohistochemistry can be used to demonstrate the presence of CMV.

Anti-CMV treatments can be effective if given early in the disease course. Treatment guidelines for severe CMV infections affecting the nervous system (eg, CMV encephalitis with obtundation) in the adult suggest combination induction therapy with IV ganciclovir 5 mg/kg and IV foscarnet 90 mg/kg twice daily to stabilize disease, if tolerated. The duration is continued until neurologic improvement is evident, which can take weeks to months. If dual therapy is not tolerated, monotherapy IV ganciclovir or foscarnet can be considered. Cidofovir is alternative for treatment for those who are unable to other options (see Table 69.2). Oral valganciclovir is recommended for CMV infections as maintenance therapy for life or until evidence of immune recovery (ie, >100 cells/μL for at least 3-6 mo) with ART is demonstrated. Oral agents for active CNS infection are unlikely to be effective.

Human Herpesvirus 6

Neurologic complications of HHV-6 only occur in the setting of immune suppression, predominantly the posttransplant population. The most frequent scenario is after hematopoietic cell transplantation, when the virus reactivates and causes a limbic encephalitis and occasionally myelitis. Incidence of HHV-6 encephalitis is approximately 4% after first transplantation and 11% in the setting of a second transplant.

Patients with HHV-6 encephalitis will develop headaches and encephalopathy, usually consisting of disorientation, short-term memory dysfunction, seizure, and depressed consciousness, which in the scenario of immune suppression should always raise red flags toward intracranial pathology. The HHV-6 replication can be detected in CSF, and especially when disparate to that in blood, this along with characteristic neuroimaging and clinical scenario support the diagnosis. The caveat is that HHV-6 reactivation is common in this setting, and so isolated detection of viral DNA is not unilaterally diagnostic.

Neuroimaging typically demonstrates bilateral mesial temporal hyperintensities perhaps with extension into the thalamus; pathologic examination has correlated increased HHV-6 DNA to these areas. Antiviral treatment, typically with foscarnet and/or ganciclovir, can reduce viral burden and prevent mortality, although long-term deficits frequently remain (see Table 69.2).

JOHN CUNNINGHAM VIRUS

The JCV is a double-stranded, circular DNA polyomavirus with an icosahedral capsid and no envelope. The virus has a worldwide distribution with a seroprevalence of 39% to 69% in adults (15% seropositive in second decade, up to 80% by the seventh and eighth decade) and viral DNA is detectable in the urine of

20% to 30% of healthy adults. There are seven types and multiple subtypes of JCV, all originating in Africa, resulting in trackable migration patterns.

Pathobiology

Initial infection with JCV occurs via ingestion or inhalation of virions leading to subacute, typically asymptomatic, infection. The JCV can infect and establish latency in the uroepithelium of the kidney or may escape into the peripheral circulation and establish latent infection in lymphoid tissues, including the bone marrow. Reactivation is precipitated in the setting of immune compromise, particularly in the setting of cell-mediated immunosuppression, where JCV can remain in circulating B cells or as cell-free virions. Although mechanisms of viral entry into the brain are not fully understood, JCV productively infects oligodendroglial cells and produces the catastrophic pathologic opportunistic infection known as progressive multifocal leukoencephalopathy (PML). More recently described, JCV can also infect cerebellar granule cells and result in a symptomatic neuronopathy (Fig. 69.13).

Original cases of PML were in patients with lymphoproliferative diseases and those on immune suppression after organ transplantation. In the 1980s, the main risk factor for PML was advanced HIV-1 infection with a CD4 count of less than 200. The early initiation of combined ART has dramatically reduced risk of PML in people living with HIV. In the last 15 years, there has been increased awareness that specific biologic agents can trigger JCV reactivation and result in PML. The most notable is natalizumab, a monoclonal antibody to $\alpha4\beta1$ and $\alpha4\beta7$ integrin and used to prevent multiple sclerosis relapses. In 2019, PML was reported in more than 750 patients taking natalizumab and requires providers to use a PML risk minimization program. Other biologic agents associated with PML risk includes but is not limited to fingolimod, dimethyl fumarate, efalizumab, and rituximab. Patients on natalizumab and other disease-modifying agents who develop PML are not systemically immune suppressed and other opportunistic infections are not common in these individuals. This suggests that PML pathogenesis is likely to be more nuanced than simply a lack of immune surveillance.

The JCV genome has three main regions that include the regulatory region (also termed *noncoding control region*), early viral gene, and late viral gene. The regulatory region is hypervariable and contains mutations that are thought to be crucial for JCV virulence and neurotropism. The late viral gene encodes for viral structural proteins such as major viral capsid protein-1, which can also acquire mutations, which may additionally contribute to neuropathogenesis. Once across the CNS barriers, the virus binds cell surface glycoproteins and can use serotonin ($5\text{-}HT_{2A}$) receptors to gain entry. Clathrin-coated vesicles initiate transport into the cell, where the virus travels in a retrograde fashion to the nucleus to establish productive infection. As mentioned earlier, although oligodendrocytes are the primary targets of infection in the brain, certain variants have the rare capability to infect cerebellar granule cells or pyramidal neurons in the cortex. Productive infection leads to cell destruction, demyelination, and macrophage infiltration. This occurs at multiple foci in the brain, and as the infection spreads, plaques form and coalesce.

Clinical Features

Clinically, symptoms manifest with dependence on localization of demyelination. Typical presentations are that of a subacute, focal deficits occurring over several weeks. Cortical weakness, ataxia, language disturbance, visual disturbance, hemispatial neglect, and impaired gait have all been well described in PML. Notably absent are signs/symptoms localizable to the spinal cord, which is spared in this entity.

The JCV is a known precipitant of the immune reconstitution inflammatory syndrome (IRIS) seen with rapid viral clearance upon initiation of combination ART in advanced HIV infection (also in the setting of natalizumab withdrawal). This entity is rare

FIGURE 69.13 Predisposing factors for progressive multifocal leukoencephalopathy (PML). Relative number of cases is depicted by arrow size. By far, advanced human immunodeficiency virus (HIV) infection or immune reconstitution has been the most frequent predisposing factor. Natalizumab therapy for the treatment of multiple sclerosis has emerged in the 21st century as an important risk factor, with duration of treatment, prior immune suppression, and John Cunningham virus (JCV) antibody positivity on treatment conferring highest risk. Hematologic malignancy has been the longest standing risk factor. Autoimmune diseases, bone marrow transplant, and other biologic or immune modulatory agents predispose as well, although autoimmune disease contribution unilaterally is controversial, as patients with PML in this setting are nearly always treated with corticosteroids or immune modulatory agents. Finally, some cases are idiopathic. Abbreviation: Abs, antibodies.

in the CNS but occurs in about 1% of treated HIV infections; when opportunistic infection is present at the time of HIV diagnosis, reduction in antigen load prior to initiation of combination ART is one strategy to prevent IRIS. In the setting of PML IRIS, however, this is not possible, as there are no known treatments available for reducing antigen burden. As such, there is no good way to prevent PML IRIS. If it does occur, treatment is supportive and most commonly involves corticosteroids to manipulate the intracranial inflammatory response (level III; expert opinion).

Diagnosis

Although brain biopsy remains the gold standard for in PML diagnosis, structural MRI is vital and assists in clinical staging of the disease. Distinguishing imaging features of PML lesions are involvement of subcortical white matter and involvement of U-fibers best seen as T2 hyperintense lesions and T1-hypointensity as part of the same lesion and diffusion-weighted imaging hyperintensity. Middle cerebellar peduncular involvement is common (Fig. 69.14). Although gadolinium contrast enhancement is rare in HIV-associated PML observed in up to 15% of cases, contrast enhancement is more often present in non–HIV-associated PML diseases, occurring in up to 40% of natalizumab-associated PML. Mass effect is not typically associated with PML lesions. In a rarer form of PML, infection of neurons in the granular cell layer of the cerebellum can result in clinical neuronopathy and detected as cerebellar atrophy on MRI. There is no current clinical role for other neuroimaging techniques (eg, positron emission tomography, magnetic resonance spectroscopy) in the diagnosis and disease monitoring in PML. In the setting of immune compromise, gadolinium enhancement is seen only about 15% of the time, whereas in the setting of immune reconstitution, this number increases but only to about 40%.

FIGURE 69.14 Axial magnetic resonance images of patients with human immunodeficiency virus (HIV)/AIDS and progressive multifocal leukoencephalopathy (PML) **(top)**, non–HIV-associated PML **(middle)**, and immune reconstitution inflammatory syndrome (IRIS) **(bottom)**. T2-weighted fluid-attenuated inversion recovery images show asymmetrical plaque-like subcortical white matter hyperintense signal **(A,E,I)**, and T1-weighted magnetic resonance imaging after administration of gadolinium shows enhancement in IRIS **(K)** and is not typically seen without immune reconstitution **(C,G)**. Diffusion restriction can be a feature of PML **(D)** but is not seen in all cases **(H,L;** signal consistent with T2-weighted shine through due to long T2 decay time **[H])**.

In a large series of HIV-associated PML cases, CSF cell counts are less than 20 cells/mm^3 with mildly elevated protein observed in over 50% of patients and normal glucose (low glucose was observed in less than 15% of patients). At early stages of PML observed in non–HIV-associated cases and in HIV-infected patients on ART, CSF JCV DNA viral load may be low or undetectable. Thus, in individuals with an MRI pattern suggestive of PML, repeat CSF analysis or brain biopsy can be pursued to make a definitive diagnosis.

The CSF studies otherwise can be normal or can show a modest lymphocytic pleocytosis with normal or slightly elevated protein concentration. These findings notably are all but indistinguishable from acute or chronic HIV meningitis. Hypoglycorrhachia is not found.

The characteristic neuropathologic features of PML are those of confluent demyelinating lesions. Grossly, irregular foci of white-matter brown-gray discolored lesions of diverse sized are typical, with occasional central necrosis and cavitation. Occasionally, these lesions may extend into the adjacent gray matter. Histologically, the lesions demonstrate demyelination, consisting of myelin loss with abundant foamy macrophages some of which contain myelin debris, associated with varying degrees of lymphocytic perivascular inflammation. In cases of IRIS, abundant $CD3^+$ and mostly $CD8^+$ cytotoxic T cells with largely perivascular distribution are seen. Atypical large pleomorphic astrocytes can be admixed with the inflammatory component. Lastly, the characteristic viral cytopathic inclusions seen in enlarged oligodendrocytes in the periphery of the lesion are homogeneous and amphophilic, occupying most of the nucleus, and consist of abundant viral particles (Fig. 69.15). Immunohistochemistry with the SV40 antibody, as well as in situ hybridization, can be used to highlight the presence of virus in infected cells.

Treatment and Prognosis

Current therapy for PML is to restore the host immune response to control JCV replication as there are no current PML-specific treatments. In HIV-infected patients who are not on suppressive ART, ART should be started immediately (level II; nonrandomized trials or observational studies with long-term clinical outcomes). The PML progression stops in more than half of HIV-infected patients started on ART, and although neurologic deficits persist, some individuals experience clinical improvement. In a case series, peripheral blood CD4 T-cell count <100 cells/mm^3 was associated with 2.7 times higher odds ratio for death when compared to higher $CD4^+$ T-cell counts; other factors associated with poor prognosis in PML includes high plasma HIV RNA levels, poor virologic response to ART, and brainstem lesions.

In cases of PML from immunosuppressive agents as in the case of organ transplantation, cessation or dose reduction should strongly be considered (level II; nonrandomized trials or observational studies with long-term clinical outcomes). Although plasmapheresis has been considered in patients on

FIGURE 69.15 Neuropathology of progressive multifocal leukoencephalopathy (PML). **A:** Luxol hematoxylin and eosin-stained section of the cerebral white matter shows sheets of macrophages and a striking loss of myelin (expected to be labeled with the blue dye in this stain) consistent with a demyelinating lesion. Focal perivascular lymphocytic infiltrates are present. **B:** Luxol hematoxylin and eosin-stained section on higher magnification demonstrates two glial cells with nuclear viral cytopathic effect consisting of glassy chromatin. **C:** Immunohistochemistry for CD3 demonstrates that most perivascular inflammatory cells are $CD3^+$ T lymphocytes. **D:** Immunohistochemistry for CD8 shows that most of the T cells are $CD8^+$ cytotoxic lymphocytes. In this case, the amount of lymphocytes is compatible with PML and was not sufficient to warrant a histologic diagnosis of the immune reconstitution inflammatory syndrome.

monoclonal antibody therapy, which may accelerate normalization of the immune system, a retrospective review concluded that mortality and morbidity were not altered with plasmapheresis (level III; expert opinion).

There are no specific treatments for PML except to reconstitute the immune system. Cytarabine, cidofovir, and mefloquine have all been studied in either randomized or open-label clinical trials and have not demonstrated efficacy against PML (performed primarily in HIV-associated cases). Therefore, treatment with these agents is not recommended (level II; nonrandomized trials or observational studies with long-term clinical outcomes). Based on in vitro data that the $5\text{-}HT_{2A}$ receptor can serve as mechanism for JCV entry, drugs that block the receptor have been used in the treatment for PML, which includes mirtazapine, olanzapine, and risperidone. There are no clinical trials supporting the use of these agents.

There has been recent interest in use of modified T cells to treat individuals with PML, with a recent case series of three patients treated with human leukocyte antigen–matched BK virus–specific T cells (BK virus is a member of the *Polymoaviridae* family). An additional case series of patients treated with programmed cell death protein 1 inhibitor has also been recently reported. Although these new therapies are compelling, no large-scale trials are currently available to determine the effectiveness of this approach and not clinically approved for use at this time.

70 Human Immunodeficiency Virus (HIV) and Acquired Immunodeficiency Syndrome (AIDS)

Anne Damian Yacoub, Deanna Saylor, Ned Sacktor, Kiran T. Thakur, Carolyn Barley Britton, and Barbara S. Koppel

KEY POINTS

1. Mild forms of cognitive impairment and distal sensory polyneuropathy are common neurologic manifestations of human immunodeficiency virus (HIV) infection.
2. The diagnosis of a primary HIV-related neurologic syndrome requires the exclusion of secondary opportunistic infections, neoplasms, and toxic/metabolic disturbances.
3. Opportunistic infections remain prevalent in HIV+ patients with advanced immunosuppression and in patients not adherent to or unable to receive antiretroviral medications.

INTRODUCTION

AIDS is the most devastating pandemic of the 20th and early 21st centuries. It was first recognized in 1981 through a growing number of reports of rare opportunistic infections, including *Pneumocystis carinii* pneumonia, and malignancies, such as Kaposi sarcoma, occurring in previously healthy men who have sex with men. Similar cases were also discovered in intravenous (IV) drug users. In 1983, human immunodeficiency virus (HIV) type-1 was isolated from human peripheral blood lymphocytes, and shortly thereafter, this retrovirus was established as the cause of AIDS. Central nervous system (CNS) complications due to infection by HIV-1 were first described early in the epidemic when severe neurocognitive disease attributable to the virus was common in individuals with profound immunodeficiency.

Classification of HIV Disease

In 1986, the Centers for Disease Control and Prevention (CDC) proposed staging criteria for HIV infection. Revisions, in 1993, added three laboratory categories that are stratified by CD4 cell numbers and three clinical categories (Table 70.1).

AIDS-defining illnesses were expanded to include positive HIV serology and pulmonary tuberculosis (TB), recurrent bacterial pneumonia, invasive cervical carcinoma, or a CD4 lymphocyte count less than 200 cells/μL. These revisions define the end stage of HIV infection and clarify the relationship of specific clinical syndromes, especially those affecting the nervous system that are not themselves diagnostic of AIDS, to advanced immunosuppression. In contrast to the CDC system, the World Health Organization (WHO) Clinical Staging and Disease Classification System revised in 2006 can be used readily in resource-constrained settings without access to CD4 cell count measurements or other diagnostic and laboratory testing methods (Table 70.2).

The WHO system classified HIV disease on the basis of clinical manifestations that can be recognized and treated by clinicians in diverse settings and by clinicians with varying levels of HIV expertise and training. This classification system guides medical management of HIV-infected persons. CD4 lymphocyte

TABLE 70.1 1993 Centers for Disease Control and Prevention (CDC) Classification of HIV Infection[a]

Laboratory Categories
Category 1—CD4 lymphocyte count >500 cells/μL
Category 2—CD4 lymphocyte count from 200 through 499 cells/μL
Category 3—CD4 lymphocyte count <200 cells/μL
Clinical Categories
Category A—asymptomatic infection, persistent generalized lymphadenopathy, and acute primary HIV infection
Category B—symptomatic conditions not included in the CDC 1987 surveillance case definition of AIDS that are judged by a physician to be HIV related or where medical management is complicated by HIV infection (eg, sepsis, bacterial endocarditis, pulmonary TB, cervical dysplasia or carcinoma, vulvovaginal candidiasis)
Category C—any of the 23 conditions listed in CDC 1987 case definition for AIDS

Abbreviation: HIV, human immunodeficiency virus.
[a]Adapted from U.S. Congress. *The CDC's Case Definition of AIDS: Implications of Proposed Revisions. OTA-BP-H-89.* Washington, DC: U.S. Government Printing Office; 1992.

TABLE 70.2 World Health Organization (WHO) Clinical Staging of Established Human Immunodeficiency Virus (HIV) Infection[a]

HIV-Associated Symptoms	WHO Clinical Stage
Asymptomatic	1
Mild symptoms	2
Advanced symptoms	3
Severe symptoms	4

[a]Adapted from World Health Organization. *HIV/AIDS Programme: Strengthening Health Services to Fight HIV/AIDS. WHO Case Definitions of HIV for Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related Disease in Adults and Children.* Geneva, Switzerland: World Health Organization; 2007. http://www.who.int/hiv/pub/guidelines/HIVstaging150307.pdf. Accessed October 12, 2020.

count levels and viral load assays have mostly supplanted staging criteria for decisions about antiretroviral therapy. Staging is still useful for prognosis and decisions about opportunistic infection prophylaxis and identifying patients most at risk for opportunistic infections and malignancy.

When a clinical suspicion of HIV exists, both a screening immunoassay as well as HIV virologic testing by polymerase chain reaction (PCR) should be performed. A negative screening immunoassay with positive viral load suggests early HIV infection. A positive screening immunoassay and positive viral load can be seen in either early or established HIV infection. A positive screening immunoassay should prompt a second, antibody only, immunoassay. A negative result on this second test suggests early or acute HIV infection; however, a second positive result does not exclude early infection, and the clinical context should be considered. In all patients with newly diagnosed HIV, genotype drug resistance testing should be performed.

EPIDEMIOLOGY

Epidemiology of HIV Infection in Adults

HIV infection is still an enduring pandemic affecting virtually all population groups and countries. According to the 2018 Joint United Nations Programme on HIV and AIDS (UNAIDS) report, in 2017 there were 36.9 million people worldwide living with HIV infection. There were estimated to be a total of 1.8 million newly infected with HIV in 2017, with 66% of these occurring in sub-Saharan Africa. AIDS-related deaths in 2017 numbered 940,000. Globally, greater reduction in mortality due to AIDS as compared to new HIV infections has seen the total number of people living with HIV rise steadily in recent years. HIV-2 is restricted to West Africa and those countries with historical and socioeconomic ties to the region and commonly co-occurs with HIV-1. Retrospective analysis of banked blood showed that HIV was present in the United States in the 1970s. In 2019, the CDC estimated the prevalence of HIV/AIDS at 1.1 million Americans (Table 70.3). Estimates were that 16% of infected individuals were unaware of their HIV status.

In 2000, AIDS became the leading cause of death among African American men aged 35 to 44 years and women aged 25 to 34 years living in the United States. The disproportionate representation of African American and Hispanic men was felt to be related to IV drug use. More recently, 2017 statistics from the CDC indicate that African Americans represent approximately 13% of the United States population in 2017 but accounted for an estimated 43% of new HIV infections. Hispanic/Latinos accounted for 26% of new HIV infections in the United States in 2016. Although affected by drug use, unprotected heterosexual activity has become the predominant transmission risk for minority women, whereas unprotected homosexual activity remains the main cause of transmissions in males. There has also been a significant increase in the incidence of HIV infection among the elderly. Nearly half of people living in the United States with HIV are age 50 years or older, although new diagnoses of HIV decline in this age category.

The introduction of combination antiretroviral therapy (cART) in 1996 profoundly changed HIV/AIDS epidemiology in the United States and other resource-rich countries. Since the introduction of cART, there has been a 38% decline in incident AIDS cases and a 67% decline in deaths from AIDS in the United States. Progress in some developing countries remains hampered by limited access to formal cART programs. Through President's Emergency Plan for AIDS Relief, UNAIDS, and the WHO as well as nongovernmental organizations and local ministries of health, there has been an increase in formal cART programs in many developing regions, with the hopes of disease stabilization in the next 5 to 10 years.

TABLE 70.3 Epidemiology of Human Immunodeficiency Virus (HIV)/AIDS: United States and Global Data: 2019 and 2018[a]

United States—Through 2018	
Adults/adolescents	1,140,400
Pediatric (<13 y)	1,323
Total	1,141,723
Demographics (Adult)	
Race	
African American	42%
Non-Hispanic white	25%
Hispanic	27%
Gender	
Men	76%
Women	24%
Global—2018	
Total cases through 2012	36,700,000
Sub-Saharan Africa	25,700,000
Asia and the Pacific	5,200,000
Number of new HIV infections in 2017	1,700,000
Deaths due to AIDS in 2017	940,000
Children with AIDS (<15 y) 2017	1,800,000

[a]Adapted from World Health Organization. *HIV/AIDS Programme: Strengthening Health Services to Fight HIV/AIDS. WHO Case Definitions of HIV for Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related Disease in Adults and Children.* Geneva, Switzerland: World Health Organization; 2007. http://www.who.int/hiv/pub/guidelines/HIVstaging150307.pdf. Accessed October 12, 2020.

The major routes of HIV transmission include sexual contact, mother to child, injection drug use with contaminated needles, and exposure to infected blood or blood products, with sexual transmission being the most common route of exposure worldwide. Worldwide, heterosexual activity is the most common mode of transmission. In 2016 in the United States, homosexual activity was the most common reason for new HIV infection (67%) followed by high-risk heterosexual behavior and injection drug use.

Recipients of blood products or clotting factor for hemophilia, or other coagulation/blood disorders, account for less than 1% of adult AIDS cases. In the United States, routine testing of blood products has largely eliminated this source of infection. Occupational exposure with validated transmission and seroconversion is well documented but rare. Most percutaneous or mucocutaneous exposures have been to blood or bloody fluid. Prospective studies of known exposures estimate the average risk for HIV transmission following percutaneous exposure ("needlestick") to be approximately 0.3%, and after mucous membrane exposure, 0.09%.

Epidemiology of HIV Infection in Children

By the end of 2016, nearly 1,300 children in the United States younger than the age of 13 years were living with HIV infection.

Most children are infected perinatally. Since 1992, perinatal transmission in the United States has declined sharply, from a peak of 1,000 to 2,000 cases annually to only 38 cases in 2006, resulting from successful implementation of CDC guidelines for maternal counseling, testing, and antiretroviral treatment. Between 2012 and 2016, perinatal diagnoses decreased by 41%.

Worldwide, however, perinatal transmission continues to post a large burden on worldwide incidence of HIV infection. In 2017, there were an estimated 1.8 million children younger than age 15 years living with HIV, with 180,000 new infections in 2017. Encouraging is that in Eastern and Southern Africa, a region wide drive to eliminate mother-to-child transmission of HIV continues to yield results. Ninety-three percent of the 940,000 pregnant women living with HIV in the region received antiretroviral prophylaxis in 2017, resulting in an average rate of mother-to-child transmission of under 10%, the lowest in the world. Perinatal infection of children depends on maternal viral load and the stage of pregnancy during which the infection is acquired. After delivery, a substantial number of children return to seronegative status. Hallmarks of early infection include developmental delay and cognitive dysfunction, loss of previously acquired milestones, and vasculopathy that can cause stroke or hemorrhage. In Africa, some studies show no difference in neuropsychological measures and school success in HIV+ children, compared with HIV-negative (HIV−) controls who have similar nutritional and socioeconomic status. However, a mortality rate of 61% by age 4 years for very ill children must qualify such a comparison.

Etiology

HIV is an enveloped RNA lentivirus. It contains an RNA-dependent DNA polymerase (reverse transcriptase) that produces a provirus capable of integrating into host cell DNA. In the target cell, the virus exists in both free and integrated states.

Human HIV infection is considered a cross-species (zoonotic) infection, arising from monkeys infected with simian immunodeficiency virus through multiple independent transmissions. Of the two recognized viral species, HIV-1 is found worldwide and is more prevalent, whereas HIV-2 is found in Western Africa and in Europe among African immigrants and their sexual partners. Sporadic cases of HIV-2 occur in the United States, but they are rare in comparison to HIV-1. A variety of evidence suggests that the AIDS pandemic most likely originated in equatorial Western Africa. HIV-1 is characterized by extensive genetic diversity and can be divided into three classes: group M (major), group O (outlier), and group N (new, non-M, and non-O). Group M is responsible for 90% of cases of HIV infection globally and is represented by nine major subtypes or clades. The HIV-1 subtypes in the United States and Europe differ from the subtypes seen elsewhere in the world. In the United States and Europe, clade B is the predominant subtype, whereas in Sub-Saharan Africa, clades A, C, and D are predominant subtypes.

PATHOBIOLOGY

Primary HIV Infection

The primary infectious event includes breach of a mucosal barrier, enhancing viral entry. Viremia drives infection and massive depletion of CD4 T cells, particularly in the gut-associated lymphoid tissue. The immune reaction to the virus causes activation of CD8 T cells and virus-specific antibody production, which in turn promotes rebound of CD4 T cells and slowed viral replication, although importantly the mucosal lymph system does not recover to its preinfective condition. Progression of HIV is caused in part by this constant immune activation that detrimentally affects the immune system through a combination of direct loss of infected CD4 T lymphocytes and bystander cell killing. Infection of CD4 lymphocytes by HIV, mediated by viral attachment to the cell surface CD4 receptor, leads to cell death. In humans, the CD4 receptor is expressed on several cell types, including neurons and glia in the brain, but there is no evidence of viral replication in cells other than lymphocytes, macrophages, monocytes, and their derivatives. In 1996, a chemokine receptor was identified as a coreceptor that is necessary for viral entry into cells. In acute and early HIV infection, an M-tropic viral strain that prefers to replicate in macrophages with the chemokine receptor CCR5 predominates (R5 strain). In advanced infection, a T-tropic viral strain that prefers T cells with the chemokine receptor CXCR4 evolves and becomes predominant (X4 virus). Genetic variation in the chemokine receptor may affect susceptibility to HIV infection. Relative resistance to infection is observed in individuals who are homozygous for a 32 base-pair deletion in CCR5. Primary HIV infection can be asymptomatic or, in 50% to 70% of the cases, results in an acute, self-limited mononucleosis-like illness with fever, headache, myalgia, malaise, lethargy, sore throat, lymphadenopathy, and maculopapular rash. Painful ulceration of the buccal mucosa may impede swallowing (odynophagia).

Acute infection is characterized by viremia, high viral replication rates (up to 1 million RNA molecules per milliliter), viral isolation from peripheral blood lymphocytes, and high serum levels of a viral-core antigen, p24. Cytotoxic lymphocytes and soluble factors from CD8 lymphocytes are effective in reducing viral load to a set point that differs for each individual. Despite the effective early immune response, there is almost simultaneous immune dysfunction. Neutralizing antibodies, initially immunoglobulin (Ig) M and later IgG, appear in 2 to 6 weeks, resulting in clearance of viremia and a decrease in serum p24 levels. Rarely, antibodies do not appear for several months or, exceptionally, not at all.

Adverse immunologic effects occur early and are more severe in symptomatic persons. An early absolute lymphopenia affects both CD4 helper and CD8 suppressor cells with lymphocyte hyporesponsiveness to mitogens and antigens and thrombocytopenia. Lymphocytosis, especially of CD8 lymphocytes, usually follows with inversion of the CD4/CD8 ratio. Atypical lymphocytes are sometimes seen. Early changes in the CD4/CD8 ratio are usually transient, but reversion to more normal values is accompanied by persistent functional abnormalities. Cutaneous anergy is a direct result of the viral effects on CD4 cells.

After acute infection and seroconversion, clinical latency may last several years before onset of symptoms due to development of secondary infection, malignancy, or neurologic disease. There is no biologic latency, however. HIV infection is a chronic, persistent infection of variable viral replication rate.

Progression to AIDs

The viral load set point after acute infection correlates with rate of progression to symptomatic infection or AIDS. Several proprietary assays provide quantitative measurement of plasma

HIV RNA. The branched (b) DNA assay detects as few as 20 to 50 copies per milliliter. Recognition of acute infection is important because early antiretroviral treatment may prevent extensive seeding of lymphoid tissues or even eliminate infection. Without treatment, viral replication is robust, and even in the absence of a decline in CD4 count may cause cardiovascular disease, nephropathy, and non–AIDS-related cancers.

It is estimated that 10 billion virions enter the plasma daily in untreated people. Virus is found mainly in tissues, not plasma; total lymphoid viral burden is 3 times that of plasma, the majority in follicular dendritic cells within germinal centers, where virus is passively adherent. The total body viral load is 100 billion HIV RNA copies. Approximately 10% of latently infected cells contain replication-competent provirus. Cellular destruction of lymphoid tissue is mediated by direct HIV-cytopathic effects, autoimmunity, and other mechanisms. Eventually, the lymphoid system is overwhelmed by the viral burden, which increases with advancing disease and culminates in AIDS.

Other factors that may augment HIV replication and the onset of symptoms include the following: the biologic variability of HIV and the appearance of increasingly virulent strains; host immunogenetics; and interactions with concomitant infection by cytomegalovirus (CMV), herpes simplex virus (HSV), hepatitis B and C viruses, human herpesvirus (HHV)-6, and human T-lymphotropic virus 1 (HTLV-1) that upregulate expression of HIV and cell-killing ability by cytokines. Cytokines and chemokines are released by immune cells in response to infection and may upregulate or downregulate viral replication.

Other immunologic abnormalities in AIDS are caused by effects of HIV on B cells or macrophages, which result in hypergammaglobulinemia, impaired antibody responses to new antigens (including encapsulated bacteria), and increased levels of immune complexes. Antibodies to platelets may cause thrombocytopenia.

Impact of Antiretroviral Therapy

cARTs and specific prophylaxis have reduced the incidence of AIDS-related opportunistic infections and neoplasms in the United States and other countries where treatment is readily available. cART refers to the use of three or more antiretroviral drugs from two antiretroviral drug classes. The major classes of antiretroviral drugs include nucleotide reverse transcriptase inhibitors, nonnucleotide reverse transcriptase inhibitors, protease inhibitors, integrase inhibitors, entry inhibitors, and fusion inhibitors. These antiretroviral drug classes interfere with different stages of HIV replication. The types of infections or neoplasms that complicate HIV infection have not changed and are similar worldwide, with varying frequencies dependent on local factors. In untreated HIV infection, *Pneumocystis carinii* pneumonia is the most common opportunistic pathogen. Other opportunistic infections are often multiple and include fungal, viral, bacterial, and parasitic organisms. Many of these infections involve the CNS, usually secondarily, but sometimes as the primary infection. For example, the papovavirus that causes progressive multifocal leukoencephalopathy (PML) causes a primary brain infection. Infections that are common in developing countries, such as trypanosomiasis, cysticercosis, and malaria, are sometimes seen in recent immigrants to the United States. Hepatitis B and C infections are important comorbid conditions, especially among those who acquire HIV from injection drug use. Kaposi sarcoma, (an AIDS-defining erythematous macular or nodular patch typically involving the face, oral mucosa, or upper trunk), Hodgkin and non-Hodgkin lymphoma, and cervical cancer, the most commonly encountered neoplasms related to immunosuppression, have become very rare in the setting of effective antiretroviral treatment. Non–AIDS-defining malignancies are now more common in treated populations, including anal cancer, lung cancer, liver cancer, and cancers of the head and neck. With the use of cART, HIV+ individuals live significantly longer, and indeed more than 75% of HIV+ individuals older than 50 years of age now die from non–HIV-related causes.

Central Nervous System Pathogenesis

HIV enters the CNS at the time of primary infection and can result in no apparent disease, in acute self-limited syndromes, or in chronic disorders. Neurologic disorders are found in up to 70% of patients in clinical series, and more than 80% of autopsy series, of AIDS patients. In 10% to 20% of patients, the neurologic disorder is the first manifestation of AIDS. Uncommonly, a neurologic disorder is the sole evidence of chronic HIV infection and the cause of death. A high prevalence of neurologic disorders is observed in all populations studied, including those in sub-Saharan Africa and Asian regions bordering the Pacific Ocean. Despite the reduction in incidence of primary HIV-related syndromes, autopsy series of cART-treated patients who died of AIDS or unrelated causes show abnormalities in most brains, which in some cases were the cause of death. Cognitive impairment or HIV-associated neurocognitive disorder (HAND) is the most important HIV-related clinical syndrome.

Evidence of early CNS invasion includes isolation of virus from cerebrospinal fluid (CSF) or neural tissue (brain, spinal cord, peripheral nerve) and intrathecal production of antibodies to HIV. How HIV enters the CNS is not known. Possible mechanisms include intracellular transport across the blood-brain barrier within infected macrophages, as free-virus seeding of the leptomeninges, or as free virus after replication within the choroid plexus or vascular epithelium. In vitro studies using a proteomic platform suggest that HIV-1–infected monocyte-derived macrophages upregulate a large number of human brain microvascular endothelial cells, causing blood-brain barrier dysfunction that facilitates the development of CNS disease. Chemokines seem to play an important role in enhanced transmigration of HIV-infected lymphocytes across the blood-brain barrier. In vitro studies show enhanced HIV-infected leukocyte transmigration in response to the chemokine CCL2 (monocyte chemoattractant protein-1) with disruption of the blood-brain barrier, enhanced permeability, reduction of tight junction proteins, and expression of the matrix metalloproteinase-2 and matrix metalloproteinase-9. In the brain, viral infection (with active replication) is detected only in microglial cells or macrophages by in situ hybridization techniques; it is not found in neurons (and rarely detected in glial cells), even though these cells have CD4 and chemokine receptors.

The high frequency of neurologic disorders in HIV infection has led to the designation of HIV as a *neurotropic virus*. The term *neurotropic* implies selective vulnerability and targeting of brain by the virus. Alternatively, the high frequency of neurologic disorders may be explained by the chronicity of infection, which results in continued seeding of the CNS and chronic immune activation. Specific neurotropism is not needed for continued accrual of neurologic damage. It has been difficult

to establish correlation of neurologic syndromes with productive viral replication in the affected tissue. There is, however, an increase in the viral burden or viral load with advancing disease that parallels dementia and other neurologic syndromes. The mechanism of neurologic injury is believed to be indirect. Potential mechanisms include immune-mediated indirect injury; restricted persistent cellular infection; cellular injury due to cytokines released by infected monocytes and macrophages; excitotoxic amino acid injury; voltage-mediated increase of intracellular calcium; free radical damage; potentiation of inflammatory damage by chemokines and lipid inflammatory mediators (arachidonic acid and platelet-activating factor); direct cellular toxicity of HIV gene products, such as the envelope gp120, tat, and gp41; and cross-reacting antibody to an HIV glycoprotein binding a cell membrane epitope, resulting in cell receptor blockade. Studies show the involvement of double-stranded RNA-activated protein kinase in apoptotic neuronal death due to HIV-gp120. This enzyme is elevated in brain tissue of patients with HIV dementia. More than one mechanism may be important. Genetic changes in the virus in the host may result in noncytopathic CNS virus with enhanced replicative capacity in monocytes and macrophages, leading to a greater viral burden in the CNS than is apparent in the periphery. Phenotypic and viral load discordance is documented in several studies of plasma and CSF.

This compartmentalization of virus may explain the occurrence of neurologic syndromes when peripheral viral replication appears to be well controlled. CSF escape, when HIV RNA is present in the CSF but undetectable in the plasma (or increased in the CSF compared to a detectable plasma level), may occur in 5% to 10% of HIV+ individuals receiving cART.

DIAGNOSIS

Initial Diagnostic Approach

The diagnostic evaluation of patients with a suspected HIV-related illness includes an enzyme-linked immunosorbent assay for HIV serology. Positive results are confirmed by Western blot. Depending on local laws, serologic tests may require informed consent and counseling. In patients with otherwise typical viral syndromes, such as aseptic meningitis or transverse myelitis, HIV infection must be suspected even in the absence of known high-risk behavior. Absence of antibodies during the acute illness does not negate the diagnosis because these disorders typically occur at the time of seroconversion. A plasma HIV viral load can be obtained if a seroconversion illness is suspected in order to achieve a definitive diagnosis. Other helpful diagnostic studies include determination of CD-lymphocyte subset ratio, serum protein electrophoresis, quantitative Igs, and platelet count.

Evaluation for specific neurologic syndromes should be preceded by a general physical examination to assist in excluding opportunistic infections or tumor. Evaluation may require biopsy of skin, lymph nodes, or bone marrow as well as chest radiography. Blood culture for viruses and fungi may also prove necessary.

Accurate neurologic diagnosis requires systematic evaluation, including assessment for the possibility of multiple diseases. CSF is most helpful in syphilis, viral, and fungal infections. PCR of CSF can be helpful for pathogenic diagnosis of HSV, varicella zoster virus (VZV), CMV, toxoplasma, and PML, but negative results do not exclude infection. CSF abnormalities are common in asymptomatic HIV infection and must be interpreted with caution in considering other possible conditions, computed tomography (CT) and, especially, magnetic resonance imaging (MRI) are useful in distinguishing focal from diffuse brain lesions. Magnetic resonance spectroscopy and thallium–single-photon emission CT (SPECT) can help in distinguishing tumor from infection. Brain biopsy may be required for definitive diagnosis of some conditions, especially PML and primary CNS lymphoma.

Myelopathy is evaluated by MRI with gadolinium to exclude a compressive lesion. CSF is a useful adjunct test to rule out infectious etiologies. Electromyography (EMG) and nerve conduction studies are useful in evaluating chronic inflammatory demyelinating polyneuropathy (CIDP), anterior horn cell disease, polyradiculopathy, peripheral neuropathy, and myopathy. Nerve or muscle biopsy may be required.

Neurological HIV-Related Syndromes

Neurologic disorders may occur at any stage from seroconversion to AIDS. Dementia and myelopathy are diagnostic of AIDS even without opportunistic infections; cognitive impairment and neuropathy are the most common direct HIV-related neurologic diseases. All levels of the neuraxis may be affected, including multisystem disorders. Neurologic disorders are likely to be transient in early HIV infection, but they become progressive or chronic with persistent infection and worsening immunosuppression in the absence of cART. In patients receiving cART, cognitive impairment and neuropathy may remain stable without progression for years and potentially decades.

The neurologic syndromes in early HIV infection are indistinguishable from disorders that occur with infection by other viruses (Table 70.4). These include aseptic meningitis, reversible encephalopathy, leukoencephalitis, seizures, transverse myelitis, cranial and peripheral neuropathy (Bell palsy, Guillain-Barré syndrome), polymyositis, and myoglobinuria. Brachial neuritis and ganglioneuritis have been reported only rarely. The course is typically self-limited, and patients often experience full neurologic recovery. Older HIV+ individuals in the cART era experience a higher incidence of neurologic disease compared to age-matched HIV-negative individuals, including nervous system infections,

TABLE 70.4 Primary Human Immunodeficiency Virus–Related Neurologic Syndromes: Acute Infection

Polymyositis
Myoglobinuria

dementia, seizures/epilepsy, and peripheral nervous system disorders. In addition, HIV+ individuals experience neurologic diagnoses at an earlier age compared to HIV-negative individuals.

CSF abnormalities (pleocytosis up to 200 cells/μL and oligoclonal bands) differentiate HIV syndromes from postinfectious disorders. Tests for HIV antibody may be negative because these syndromes may precede or accompany seroconversion, and the tests must be repeated in several weeks. If acute HIV infection is strongly suspected, p24 antigen and viral load assay should be considered if serology is negative. Hepatitis B and hepatitis C serology should be determined in all HIV-seropositive patients. Early antiretroviral therapy may be offered to decrease the high viral load typical of acute infection quickly, thereby lowering the viral load set point. No specific treatment is indicated for these self-limited disorders except that plasmapheresis or Ig are used in cases of Guillain-Barré syndrome and steroids for polymyositis.

In chronic HIV infection, neurologic disorders may accompany systemic HIV disease or secondary disorders (Table 70.5).

Chronic or recurrent CSF pleocytosis sometimes occurs with meningeal symptoms but is often asymptomatic. Chronic pleocytosis does not predict any specific neurologic complication. Ascribing CSF pleocytosis to HIV infection requires exclusion of secondary pathogens or tumor. In a cross-sectional study, HIV-related CSF pleocytosis was uncommon in individuals with blood CD4 counts below 50 cells/μL or in those on effective antiretroviral therapy.

HIV Associated Neurocognitive Disorder

Cognitive impairment is a well-recognized complication of chronic HIV infection in all populations; it can range from mild to severe (Table 70.6). HIV-associated dementia refers to HIV+ individuals with moderate-to-severe cognitive impairment on neuropsychological testing and marked difficulties in activities of daily living due to the cognitive impairment. HIV-associated dementia, known variously as *HIV-1–associated dementia complex*, *HIV dementia*, or *AIDS dementia complex*, is diagnostic of AIDS. Older designations are subacute encephalitis, subacute encephalopathy, or HIV encephalitis. In the pre-cART era, HIV dementia, the most severe stage of HAND, was a common stage of cognitive impairment among HIV+ individuals with advanced immunosuppression. In HIV+ individuals on cART, HIV dementia is rarely seen (2%-5% of HIV+ individuals on cART), and less severe stages of HAND such as asymptomatic neuropsychological impairment (ANI) and HIV-associated mild neurocognitive disorder (MND) are the most common stages of cognitive impairment. HAND, including all three stages (ANI, MND, and HIV dementia), may be seen in 30% to 50% of HIV+ individuals with advanced infection. Peripheral neuropathy coexists in 25% of patients.

TABLE 70.5 Primary HIV Related Neurologic Syndromes: Chronic Infection

Persistent or recurrent meningeal pleocytosis with or without meningeal symptoms
Diffuse and focal cerebral syndromes
Dementia, static or progressive with or without motor signs
Mild cognitive impairment, neuropsychological test criteria only
Organic psychiatric disorder
Cerebrovascular syndromes
Cerebellar ataxia
Seizure disorder
Multisystem degeneration
Chronic progressive myelopathy
Cranial and peripheral neuropathies
Bell palsy
Hearing loss

Severe Manifestations
HIV-1–associated dementia
Mild Manifestations
HIV-1–associated mild neurocognitive disorder
Asymptomatic neuropsychological impairment

The International HIV Dementia Scale is a brief screening test which can be performed by nonneurologists and has been validated as a potential screening test for dementia in HIV+ individuals in resource-limited settings. There are several scales for classification of HIV-associated cognitive impairment, including revision of the AIDS Task Force of the American Academy of Neurology criteria.

HIV dementia in the pre-cART was an insidiously progressive subcortical dementia with prominent motor signs including slow movements, tremor, parkinsonian features, leg weakness, and gait ataxia. However, in the cART era, HIV dementia now presents with more prominent cortical features and less prominent motor signs. Early symptoms include slow thinking, poor concentration, forgetfulness, apathy, social withdrawal, and diminished libido. Neuropsychological testing manifestations of HAND include poor executive function, impaired speed of information processing, and poor mental flexibility. Memory is relatively spared until the later stages of the dementia; impaired memory reflects problems with retrieval rather than encoding, in contrast to Alzheimer disease. Psychiatric syndromes, such as psychosis, depression, or mania, are sometimes profound and may be the first manifestation of HIV infection. There may also be headaches, seizures, or frontal release signs. Although the disorder is usually progressive in HIV+ individuals not on cART, some patients on cART develop a static level of disability, and others may improve in response to medical treatment for HIV or complicating disorders. When progressive, the disease culminates in akinetic mutism, an immobile bedridden state with global cognitive impairment and urinary incontinence.

In children, there may be a similar static or progressive encephalopathy. Most affected children meet criteria for AIDS, but progressive encephalopathy can occur before immunologic dysfunction is severe. Neurologic findings include intellectual

deterioration, microcephaly, loss of developmental milestones, and progressive motor impairment that may culminate in spastic quadriparesis and pseudobulbar palsy. Seizures are usually due to fever. Myoclonus and extrapyramidal rigidity are rare.

CSF Examination

The CSF is usually normal or shows a mild pleocytosis, protein elevation, and oligoclonal bands. Virus can be cultured from CSF. In HIV+ individuals not on cART, both CSF and plasma viral load correlate with occurrence of dementia but may be discordant in some cases where CSF load is greater than plasma. In HIV+ individuals on cART, CSF and plasma viral load do not correlate with HAND stage. Most HIV+ individuals on cART have an undetectable CSF HIV RNA. CSF markers of immune activation, such as HIV p24 antigen, β_2-microglobulin, tumor necrosis factor, and antimyelin basic protein, and markers of oxidative stress such as CSF sphingomyelin and ceramide in cART-treated HIV+ individuals do not correlate with severity of dementia. None of these markers is predictive of, or specific for, dementia. CSF markers such as neopterin lack predictive value and specificity but can correlate with severity of dementia. Elevated levels of CSF neurofilament protein, a marker of axonal injury, are found in HIV-infected patients with dementia. Plasma neurofilament protein levels which correlate with CSF neurofilament protein levels are currently being evaluated as a potential peripheral surrogate marker of HIV dementia.

Imaging

In adults, CT or MRI scans show cortical atrophy, basal ganglia atrophy particularly within the caudate nucleus, and ventricular dilatation, sometimes with white matter changes. On CT, there is attenuation of white matter; MRI shows hyperintense white matter lesions on T2-weighted and proton density sequences, ranging from discrete foci to large confluent periventricular lesions (Fig. 70.1). CT in children shows basal ganglia calcification and cerebral atrophy. MRI white matter changes may not correlate with dementia and may disappear spontaneously or with antiretroviral therapy. The primary role of neuroimaging with CT or MRI in the evaluation of an HIV+ patient is to exclude a CNS focal lesion such as a CNS opportunistic infection, malignancy, or stroke.

Abnormalities in functional neuroimaging are detected in HIV-infected individuals, whether they have dementia or not. The abnormalities become worse or change with progressive cognitive impairment. Fluorodeoxyglucose–positron emission tomography shows relative hypermetabolism in the thalamus and basal ganglia in HIV-infected individuals. Progressive dementia is accompanied by cortical and subcortical hypometabolism. SPECT shows multifocal cortical perfusion deficits in the frontal lobes, worse in those with dementia. Cerebral metabolite abnormalities demonstrated by magnetic resonance spectroscopy include elevated myoinositol and choline levels in frontal white matter indicative of glial proliferation in patients with mild cognitive impairment. Severe dementia is associated with decreased levels of *N*-acetyl aspartate, a neuronal marker. Diffusion tensor imaging may show abnormalities in white matter tracts in patients with HAND. Dynamic cerebral blood volume studies by functional MRI (fMRI) show increased cerebral blood volume in deep and cortical gray matter in HIV-positive individuals and even greater increases in the deep gray matter of those with dementia. Continuous arterial spin label MRI showed reduced caudate blood flow and volume in patients with cognitive impairment. Functional neuroimaging abnormalities may improve with antiretroviral treatment.

Pathology

Pathologic abnormalities in brain include microglial nodules, multinucleated giant cells, focal perivascular demyelination and gliosis, and neuronal loss in frontal cortex. Although there is often

FIGURE 70.1 Human immunodeficiency virus–positive subject with progressive dementia. T1-weighted **(A)** and T2-weighted **(B)** magnetic resonance imaging scans show ventricular enlargement and cortical atrophy, particularly in the frontal lobe. There is also some mild periventricular T2 hyperintensity.

no correlation between the severity of these pathologic changes and the severity of dementia, studies suggest that neuronal injury may be missed by standard pathologic survey techniques. In a prospective study, severity of neurocognitive impairment was correlated with microneuroanatomic injury to dendritic structures that resulted in dendritic simplification but not to viral burden or presence of microglial nodules and multinucleated giant cells. Astrocyte cell death through apoptotic mechanisms may reduce the neuroprotective functions of this cellular population. In vitro studies show that soluble Fas ligand from HIV-infected macrophages triggers apoptosis of uninfected astrocytes. A study of pre-cART HIV-infected patients with dementia showed elevated CSF soluble Fas ligand levels in this group compared with HIV-negative controls and HIV+ nondemented patients. More prospective data are needed to understand the role of apoptosis in HIV dementia and the utility of markers for apoptosis as predictors of dementia.

Differential Diagnosis

The diagnosis of HIV-associated dementia requires exclusion of secondary opportunistic infections or neoplasms. Other confounding variables include drug use, vitamin B_{12} deficiency, metabolic disorders, concurrent infections such as hepatitis C infection, CNS side effects of medications (eg, efavirenz which can cause CNS side effects in 50% of HIV+ individuals after initiation, medications with anticholinergic properties), and age-related comorbidities in an aging HIV-infected population due to successful antiretroviral treatment.

Management

In most studies, antiretroviral therapy reduces the incidence and mortality of HIV dementia. The primary treatment for HAND is cART, which is associated with cognitive improvement in the majority of antiretroviral-naïve HIV+ individuals. Treatment of comorbid conditions frequently associated with HAND such as depression is also beneficial. A trial of the selective serotonin reuptake inhibitor, paroxetine, showed a trend for improved cognitive performance even after controlling for depression status, but further studies are warranted. Several additional adjunctive treatments targeting specific immune and inflammatory products are currently being evaluated.

Antiretroviral therapy using drugs with good CNS penetration may benefit the symptomatic patient with CNS virologic escape, but some studies suggest that the beneficial effect of treatment is independent of CNS penetration. A randomized clinical trial of cART with good CNS penetration compared to cART with poor CNS penetration showed no clinical benefit for the group randomized to cART with good CNS penetration. Suppression of viral replication in both the blood and CSF is critical for effective treatment of HAND. Initiation of cART is usually associated with immune system recovery and cognitive benefits. However, some HIV+ individuals after initiation of cART may experience clinical deterioration despite recovery of the immune system from immunodeficiency, a condition known as *immune reconstitution inflammatory syndrome* (IRIS). When IRIS involves the CNS, opportunistic infections of the CNS such as cryptococcal meningitis or PML may present. In addition, an acute syndrome of fulminant HIV encephalitis can occur in rare cases in which cognition worsens despite virologic suppression and immune system recovery. Risk factors for IRIS include a low CD4 nadir at initiation of cART, the presence of an underlying opportunistic infection, and a sharp decline in viral load after starting cART. Corticosteroids have been used in HIV+ individuals with noninfectious encephalitis after cART initiation with clinical improvement in some cases. Additional studies of the role of corticosteroids for the treatment of IRIS are needed.

HIV eradication strategies (eg, "shock and kill") are currently being evaluated to treat HIV infection in research studies in an attempt for a cure. As part of these eradication strategies, latent viral reservoirs are activated with a latency-reversing agent and then targeted for elimination. It should be recognized that the CNS may serve as a potential reservoir site, and the CNS should be closely monitored, as these eradication strategies are rolled out.

Stroke

Most studies show an association with stroke incidence and HIV status in the post-cART era that extends beyond traditional risk factors including hypertension, dyslipidemia, diabetes mellitus, and smoking, particularly in younger patients. Although modification of these risk factors is an important strategy to decrease stroke risk among HIV-infected individuals, studies have demonstrated an excess risk of stroke in HIV infection. Multiple mechanisms unique to HIV infection may cause an increased stroke risk. Impaired fibrinolysis resulting in a hypercoagulable state may occur. Intracranial vasculopathy has been described in untreated, severely immunocompromised HIV-infected individuals with and without strokes, often in combination with aneurysmal arteriopathy and, at times, with concomitant infections including VZV and CMV. Marked clinical and radiographic improvement of vasculopathy documented after initiation of cART suggests that this mechanism is likely of considerably less clinical relevance for virologically suppressed individuals on cART. In fact, the epidemiology of stroke in HIV-infected individuals has shifted as the average age of persons living with HIV has increased, the use of cART has become more widespread and the prevalence of opportunistic infections has decreased. A further shift has been the increasing prevalence of traditional risk factors in lower-income and middle-income countries due to globalization. In addition, cumulative exposure to cART may lead to a rise in vascular risk over time. Insulin resistance as well as dyslipidemia due to antiretroviral therapy may also add to stroke risk. More recently, it has been suggested that women with HIV may have increased relative risk of stroke as compared with men, although the mechanisms for this remain unclear. In addition, stroke syndromes may follow secondary infections or neoplasms, such as cryptococcus or other fungi, toxoplasmosis, TB, herpes zoster, CMV, syphilis, or lymphoma. Other causes include HIV-related vasculitis, cardiogenic emboli, thrombogenic conditions such as hyperviscosity, disseminated intravascular coagulation, and the presence of lupus anticoagulant. Cerebral hemorrhage may follow HIV-associated thrombocytopenia or toxoplasmosis.

Evaluation of cerebrovascular syndromes includes screening for classical risk factors including high blood pressure, impaired glucose tolerance, and hyperlipidemia. Additional studies which should be obtained include imaging; CSF examination; cultures for viruses, bacteria, mycobacteria, and fungi; serum and CSF antibodies for cryptococcus, syphilis, and toxoplasmosis; plasma and CSF HIV viral load; PCR of CSF for suspect pathogens; echocardiography; carotid Doppler; lipid profiles; coagulation profiles; platelet count; and determination of procoagulants. If vasculitis is suspected, angiography or brain or meningeal biopsy may be useful. Additionally, intracranial vessel wall (black blood) MRI is an emerging tool, which may aid in the differentiation between stroke due to vasculitis versus accelerated intracranial atherosclerosis. Management is directed to the underlying mechanism and may include a change in antiretroviral therapy.

Seizures

The prevalence of seizures and epilepsy in patients with HIV is significantly higher than the general population, with higher mortality rates. Seizure activity complicating HIV infection should raise the suspicion for an underlying structural brain lesion, especially in the setting of focal seizure activity, in patients whose CD4 counts are less than 400, and if focal neurologic signs are present on examination. If seizures are generalized, common etiologies include an underlying metabolic derangement or diffuse meningoencephalitis. Underlying infectious and noninfectious causes to consider, especially in those patients with low CD4 counts, include toxoplasmosis, cryptococcoma, primary CNS lymphoma, and PML. In a study of 100 consecutive cases, secondary pathogens were identified in 53% and HIV encephalopathy in 24%; there was no identified cause in 23%. In another study, status epilepticus was associated with CNS infection in a third of patients, most commonly toxoplasmosis. It has, therefore, also been suggested that HIV infection alone may be the sole cause of seizures. Seizure is a common disease-defining presentation, reported to occur as the initial presentation of HIV in 18% of patients. A recent meta-analysis including 6,639 cases, comprising studies from the United States, Europe, Asia, and Africa, found the pooled prevalence of seizures in HIV to be 62 per 1,000, and the pooled incidence to be 60 per 1,000. Sixty-three percent of patients experienced seizure recurrence, and 82% of patients had a diagnosis of AIDS at time of first seizure. Infections were the primary identifiable etiology, with toxoplasmosis diagnosed in 21% of patients and cryptococcus in 14%. An additional 14% of patients were found to have PML. Thirty-two percent of patients were not found to have an etiology, with seizures hypothesized to be caused by HIV alone.

The diagnosis of seizures in HIV patients includes basic laboratory parameters, drug levels if available, neuroimaging, lumbar puncture, and electroencephalogram. If antiepileptics are indicated, one should consult guidelines for the initiation of antiepileptic medications and dosage adjustments of antiretroviral drugs due to antiepileptic drug–antiretroviral drug interactions by a joint panel of the American Academy of Neurology and the International League Against Epilepsy.

Leukoencephalopathy

Leukoencephalopathies in acute or chronic HIV infection include acute fulminating and fatal leukoencephalitis, multifocal vacuolar leukoencephalopathy presenting as rapid dementia, and a relapsing-remitting leukoencephalitis that may simulate multiple sclerosis. The pathogenesis of these syndromes is uncertain. A severe demyelinating leukoencephalopathy with intense perivascular infiltration by HIV-gp41 immunoreactive monocytes/macrophages and lymphocytes is described in patients who failed highly active antiretroviral therapy treatment despite good virologic response in one case. Some speculate this illness is a form of IRIS.

Movement Disorders

Movement disorders in patients with HIV infection were frequently described in the pre-cART era, including patients presenting with tremors, chorea, facial or paroxysmal dyskinesias, and athetosis, most commonly associated with opportunistic infections such as toxoplasmosis. Segmental or generalized myoclonus has also been described. Toxoplasmosis and cryptococcus have a predilection for the basal ganglia, and in particular, toxoplasmosis can be associated with hemichorea-hemiballismus due to lesions in the subthalamic nucleus or its connections. Treatment of the underlying opportunistic infection may not necessarily reverse the movement disorder. Hyperkinetic movement disorders (tremors) or parkinsonism can not only be observed in the context of opportunistic infections but also as an initial clinical manifestation of the viral infection in the post-cART era. The movement disorder associated with HAND is best described as psychomotor retardation, with slow rapid alternating movements, increased muscle tone, and mild bilateral postural tremor. Cognitive decline typically precedes tremor and gait disturbance. Interestingly, there appears to be a greater susceptibility to drug-induced parkinsonism in HIV-infected patients, likely related to dopaminergic neuron dysfunction from primary HIV infection, which occurs early in infection. Movement disorders related to peripheral neuropathy have also been frequently described in HIV, including restless legs syndrome as well as painful legs and moving toes syndrome.

Myelopathy

HIV can involve any segment of the spinal cord and adjacent nerve roots, leading to myelopathy, to radiculomyelopathy, and to involvement of the gray or white matter of the spinal cord. There are some reports that at the time of seroconversion or early in infection, an HIV-associated transverse myelitis can develop. In contrast, in patients who have a CD4 count of less than 500, the differential diagnosis for myelopathy in the context of HIV infection includes HIV myelitis, vacuolar myelopathy, primary CNS lymphoma, CMV radiculomyelitis, HSV sacral radiculomyelitis, VZV myelitis, spinal cord syphilis, and spinal cord TB among others. The myelopathy syndrome most unique to HIV of these is a chronic progressive myelopathy, an AIDS-defining illness that is characterized by progressive spastic paraparesis, ataxia, and sphincter dysfunction. Vacuolar myelopathy presents with a subacute onset of clinical signs and symptoms, developing over weeks to months. Common symptoms include bilateral lower extremity weakness with spasticity. Patients also experience bowel, bladder, and erectile dysfunction with variable sensory disturbances. Deep tendon reflexes are hyperactive with an extensor plantar response. Pathologic findings are similar to those of subacute combined degeneration due to vitamin B_{12} deficiency and include vacuolar change with intramyelin swelling or demyelination that is most severe in the lateral and posterior columns. Microglial nodules and giant cells are sometimes seen, and HIV can be sometimes cultured or detected by hybridization techniques, although there is no known correlation between HIV levels in the CSF and the presence or severity of vacuolar myelopathy. Pathologic abnormalities are more common than clinical symptoms. Diagnosis requires ruling out causes by measuring serum vitamin B_{12} levels, copper levels, rapid plasma reagin, and HTLV-1 antibodies before making the diagnosis. Lumbar puncture should be performed to rule out infection with HSV, VZV, CMV, and neurosyphilis. In HIV-associated vacuolar myelopathy, the CSF may be normal, or it may show mild pleocytosis with mild elevation in protein. Neuroimaging should be performed, although it is important to note that the spinal MRI may be normal, or it may show spinal atrophy or patchy abnormalities on T2-weighted images. Somatosensory-evoked potentials help to confirm myelopathy, whereas nerve conduction studies can detect coexistent neuropathy if present. No specific treatment is available for myelopathy. The impact of cART is unknown. A pilot study assessing the role

of intravenous immunoglobulin (IVIG) remained inconclusive. Antispasticity drugs such as baclofen or bladder relaxants such as imipramine must be used cautiously to avoid sedation or exacerbating weakness.

Motor Neuron Disease

Several cases of an amyotrophic lateral sclerosis (ALS)-like illness have been reported as the initial neurologic syndrome in patients with varying degrees of immunosuppression, ranging from profoundly reduced to near-normal CD4 lymphocyte levels. Clinically, HIV-associated ALS differs from sporadic ALS in that the patients present with symptoms at a younger age, have a more rapid progression, have a high CSF protein, and may recover after initiation of cART. There are additional descriptions of a solely lower motor neuron phenotype. EMG features have been shown to be consistent with ALS in one series of six patients. It is important to note that because of the potential reversibility of ALS-like symptoms in HIV infection, testing for HIV infection is generally recommended in younger patients presenting with motor neuron symptoms. The actual pathology underlying HIV-associated motor neuron disease has not been well defined.

Peripheral Neuropathy

Distal sensory polyneuropathy (DSPN) is one of the most common neurologic manifestations of HIV infection with more than 50% of patients with advanced HIV having evidence of DSPN on neurologic examination. It may be caused by antiretroviral toxicity, or HIV-mediated inflammatory pathways. Risk factors for development of sensory neuropathy include advanced age, lower CD4 nadir, current antiretroviral therapy use, and past "D-drug" use (specific dideoxynucleoside analog antiretrovirals, ie, ddI [didanosine], ddC [zalcitabine], and d4T [stavudine]). Overall, the incidence of neuropathy has increased because of the longer survival of HIV-infected patients, likely related to comorbidities including diabetes mellitus, alcohol abuse, and vitamin B_{12} deficiency. Symptoms are typically symmetric, predominantly distal and sensory. Patients may experience numbness, tightness, pain, burning, or hyperalgesia in the feet. Signs include stocking-glove sensory loss, mild muscle wasting and weakness, and loss of ankle jerks. Conduction studies show sensorimotor neuropathy with mixed axonal and demyelinating features; however, they may also be normal. Both clinically and with nerve conduction studies, HIV-related DSPN is indistinguishable from the neuropathy due to nucleoside reverse transcriptase inhibitors, although neuropathy due to nucleoside reverse transcriptase inhibitors may develop more rapidly. The association between DSPN and CD4 count is diminishing in cART era, with some studies showing an association between higher CD4 count and DSPN. A skin biopsy may show evidence of small-fiber neuropathy. Pathologic findings include axonal degeneration, loss of large myelinated fibers, and variable inflammatory cell infiltration. CSF may be normal or show mild pleocytosis and elevated protein. HIV can rarely be cultured from nerve, but the cellular localization of the virus is not known. The neuropathy may be mediated by the binding of gp120 envelope viral glycoprotein to sensory ganglion cells.

Neuropathic pain is associated with significant disability in daily activities, unemployment, and overall reduced quality of life. It is sometimes responsive to anticonvulsants (gabapentin, pregabalin, lamotrigine), tricyclic antidepressants, selective serotonin-norepinephrine reuptake inhibitors (duloxetine), topical anesthetic patches or creams, high-concentration capsaicin patch, and nonsteroidal or narcotic analgesics. There are also reports that smoked cannabis is effective for pain but may be associated with CNS side effects.

Other clinical manifestations of HIV infection include mononeuropathies, mononeuritis multiplex, inflammatory demyelinating polyneuropathy, and ganglioneuritis. Inflammatory demyelinating polyneuropathy may occur in its acute form, shortly after seroconversion when the CD4 count is still more than 500 cells/μL. Chronic inflammatory demyelinating polyneuropathy may also occur early in infection, when there is immune dysregulation. It is distinguished from Guillain-Barré syndrome by a subacute or progressive course and variable response to corticosteroids, IVIG, or plasmapheresis. Electrodiagnostic studies show demyelination with variable axonal damage. Histopathologic studies reveal epineurial inflammatory cell infiltrates, demyelination, and axonal degeneration. CSF may show a pleocytosis, which is not typically characteristic of acute inflammatory demyelinating polyneuropathy. The treatment of acute inflammatory demyelinating polyneuropathy with close monitoring and IVIG or plasmapheresis is the same regardless of HIV status. Mononeuropathies due to entrapment neuropathies are also commonly seen in patients with HIV infection. It is important to note that focal cranial neuropathies warrant further evaluation including neuroimaging and CSF analysis. Mononeuropathy multiplex due to peripheral nerve infarction associated with vasculitis is rarely described secondary to primary HIV infection and is more frequently described with CMV opportunistic infection as described in the following text.

Myopathy

HIV-associated myopathy may range from mild symptoms to severe rhabdomyolysis, with HIV-associated polymyositis being the most frequent clinical syndrome. HIV-related myopathy may also be due to zidovudine therapy, vasculitis, and infection (*Staphylococcus aureus*, *Mycobacterium*, CMV, and *Toxoplasma*). The presentation varies based on the underlying cause, and serum CK levels are variably elevated. HIV-associated polymyositis is clinically and pathologically similar to autoimmune polymyositis and is characterized by proximal limb weakness, mild creatine kinase elevation, and myopathic features on EMG. The mechanism by which HIV leads to inflammatory myopathy is not fully understood, but a T-cell–mediated and major histocompatibility complex I–restricted cytotoxic process triggered by HIV has been proposed. HIV-associated myopathy has also been described as part of an IRIS. Although treatment is not established in HIV-associated myopathy, patients may respond to steroids or IVIG. Stavudine (d4T) can cause HIV-associated neuromuscular weakness syndrome, which is characterized by a rapidly progressive weakness, resembling Guillain-Barré syndrome, with associated lactic acidosis due to mitochondrial dysfunction. Some patients respond well to steroid therapy without accelerated progression of HIV disease.

Opportunistic Infections

The spectrum of viral, bacterial, and fungal opportunistic infections, well described for their devastating consequences prior to the cART era, remain prevalent in many countries where cART medications remain poorly accessible, in patients not adherent to their HIV drug regimen, and as immune reconstitution phenomenon (**Table 70.7**).

Meningitis may be caused by such viruses including HSV, VZV, CMV, Epstein-Barr virus; fungi (*Cryptococcus*, *Histoplasma*,

TABLE 70.7 Secondary Neurologic Syndromes in Human Immunodeficiency Virus Infection and AIDS: Opportunistic Infections and Neoplasms

Leptomeninges	
Viral	CMV, HSV, VZV, EBV, hepatitis B
Fungal	*Cryptococcus, Histoplasma, Coccidioides, Candida*
Bacterial	*Listeria, Treponema pallidum*, pyogenic bacteria (*Salmonella, Staphylococcus aureus*), atypical or conventional mycobacteria
Neoplasm	Lymphoma
Cerebral Syndromes	
Diffuse encephalopathy or encephalitis	
Viral	CMV, HSV, VZV, hepatitis C
Bacterial	Atypical mycobacteria
Parasitic	Acanthamoeba, toxoplasma
Neoplasm	Lymphoma
Focal Cerebral Syndromes	
Viral	HSV, VZV, PML
Fungal	Abscess due to *Cryptococcus, Candida, Zygomycetes, Histoplasma, Aspergillus*
Bacterial	Abscess due to pyogenic bacteria, mycobacteria (tuberculoma), *Listeria, Nocardia*
Parasitic	*Trypanosoma cruzi, Taenia solium*, toxoplasma
Neoplasm	Primary or metastatic lymphoma, glioma, metastatic Kaposi sarcoma
Cerebrovascular Syndromes and Seizures	
Viral	VZV, HSV, PML
Fungal	*Cryptococcus, Aspergillus*
Bacterial	*T pallidum, Mycobacterium tuberculosis*
Parasitic	*Toxoplasma*
Neoplasm	Lymphoma, lymphomatoid granulomatosis, metastatic Kaposi sarcoma
Other	Cerebral hemorrhage, cardiac emboli, vasculitis
Movement Disorders	
Viral	PML, HIV
Bacterial	CNS Whipple disease
Parasitic	*Toxoplasma*
Neoplasm	Primary CNS lymphoma
Spinal Cord Syndromes	
Viral	VZV, CMV, HSV, HTLV-1
Bacterial	Mycobacteria, myogenic bacteria, *T pallidum*
Parasitic	Toxoplasmosis
Neoplasm	Lymphoma, Kaposi sarcoma
Cranial and Peripheral Neuropathy	
Viral	CMV (retinitis, polyradiculitis, mononeuritis multiplex)
Bacterial	*T pallidum*
Fungal	*Candida* (retinitis)
Parasitic	*Toxoplasma* (retinitis)
Myositis	
Bacterial	*Staphylococcus aureus*, mycobacteria
Parasitic	*Toxoplasma*

Abbreviations: CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HTLV-1, human T-lymphotropic virus 1; PML, progressive multifocal leukoencephalopathy; VZV, varicella zoster virus.

Coccidioides, *Candida*); bacteria (*Listeria*, *Treponema pallidum*, atypical or conventional mycobacteria, pyogenic bacteria such as *Salmonella*, *S aureus*); and neoplasm (carcinomatous meningitis due to lymphoma).

Focal brain syndromes may be caused by *Toxoplasma*, PML, and abscesses related to *Nocardia*, *Listeria*, *Taenia solium*, *Candida*, *Cryptococcus*, *Histoplasma*, *Aspergillus*, *Coccidioides*, *Mycobacterium tuberculosis*, atypical mycobacteria, and pyogenic bacteria.

Viral Infections

The pattern of opportunistic viral infection associated with AIDS has changed since the introduction of effective HIV therapy. Early in the AIDS epidemic, syndromes such as shingles or recurrent aseptic meningitis raised suspicion of an immunodeficient state, and the encephalitis eventually attributed to HIV itself was initially attributed to CMV infection. In contrast, contemporary concerns include facilitation of HIV spread by simultaneous herpes genital infection, use of vaccinations in households of AIDS patients, and other epidemiologic considerations. However, in severely immunosuppressed patients, viral infections of the nervous system remain prominent. For further information about viral infections, see Chapter 69.

Progressive Multifocal Leukoencephalopathy

PML was recognized early in the HIV pandemic as a complication of AIDS in profoundly immunosuppressed patients. PML is caused by John Cunningham (JC) virus, which is a ubiquitous polyomavirus. CNS disease is characterized by lytic infection of oligodendrocytes causing demyelination. Clinically, patients develop a subacute neurologic decline with focal neurologic symptoms and signs. Localization is hemispheric in 85% to 90% of cases; the posterior fossa is affected in the remainder. Rare cases of spinal cord PML have also been reported. Focal or generalized seizures occur in 6% of patients and become more common as the disease progresses. Imaging shows hypodense subcortical lesions on CT, and T2 hyperintense lesions on MRI that spare the cortical gray matter and have corresponding T1 hypointensity (Fig. 70.2). In PML-IRIS, MRI may show contrast enhancement on T1 postgadolinium sequences, most commonly associated pathologically with CD8+ T cells infiltrating the perivascular spaces. JC virus has also been reported to cause granular cell neuronopathy leading to a progressive cerebellar syndrome as well as meningitis. CSF analysis should be performed for JC virus detectable on PCR, although a negative study does not exclude the diagnosis, and repeat testing and potentially a brain biopsy are recommended if clinical and radiographic imaging is consistent with the diagnosis.

cART has led to significant improvement in survival, although patients are often left with serious neurologic sequelae. Despite anecdotal reports of efficacy, clinical trials have not shown any benefit from IV or intrathecal cytosine arabinoside, topotecan, mefloquine, or cidofovir. In vitro reports suggest mirtazapine blocks JC virus uptake into new oligodendrocytes, and anecdotal reports have suggested this may be beneficial clinically. However, it has never been studied in a randomized trial. Immune reconstitution following antiretroviral therapy favorably impacts the clinical

FIGURE 70.2 A 38-year-old woman with a history of human immunodeficiency virus/AIDS recently resumed antiretroviral medication with CD4 count rising from 23 to 78 cells/μL in 2 months, viral load of 340,000, presenting with left-sided weakness that became worse after 2 weeks and diagnosed with progressive multifocal leukoencephalopathy as a complication of immune reconstitution inflammatory syndrome. Fluid-attenuated inversion recovery **(A)** hyperintense lesions in bilateral frontoparietal white matter extending to the subcortical regions, larger on the right than left, associated with irregular peripheral enhancement **(B)**. (Courtesy of Dr. Doris Lin, Department of Radiology, Johns Hopkins University School of Medicine.)

course in some but not all patients with PML. The IRIS with either emergence or clinical progression of PML has been reported. When PML is the AIDS-defining illness, improved prognosis is associated with CD4 cell counts greater than 300 cells/μL, evidence of inflammatory response indicated by gadolinium enhancement on MRI, and reduction in the JC virus viral load in CSF.

Varicella Zoster Virus

VZV, the causative agent of varicella (chicken pox) and herpes zoster (shingles), is common in the general population with a lifetime prevalence of 15% to 30%. A ubiquitous latent virus, VZV remains dormant in the dorsal root ganglia after primary infection, characterized by fever and vesicular rash, most commonly occurring in early childhood. In severely immunosuppressed patients, the infection is reactivated leading, in some cases, to disseminated diseases with manifestations including pneumonia, diffuse rash, and visceral involvement.

Shingles beginning with painful dysesthesias or paresthesias (often described as itching) is followed in 7 to 10 days by a contagious vesicular rash that eventually crusts. The acute phase lasts up to a month and may be followed by chronic neuralgic pain for years, although this is less likely if effective antiviral treatment is started promptly. Location is most commonly thoracic, followed by cervical and trigeminal dermatomal distributions. Neurologic complications in addition to postherpetic neuralgia include large- or small-vessel stroke due to vasculitis induced in the vessel wall by the virus, myelitis, segmental myoclonus, and meningitis or encephalitis. *Zoster ophthalmicus*, which involves the first division of the trigeminal nerve, can lead to blindness from corneal scarring. Neurologic manifestations may occur weeks to months after a typical shingles rash.

Diagnosis is made by CSF PCR analysis or antibody detection. VZV antibodies can be detected in 2.5% to 7% of HIV-infected patients with meningitis, encephalitis, myelitis, or retinitis who have a history of shingles. MRI of the brain or spinal cord may show focal or meningeal enhancement. In patients with encephalitis, CSF shows a mononuclear pleocytosis, increased protein, and, sometimes, low glucose.

Treatment of VZV complications with acyclovir or famciclovir should be started within 72 hours of the rash to prevent pain. Vaccination with two doses of live attenuated virus is recommended even in HIV-infected patients if their CD4 cell count is greater than 200 because this may decrease future complications.

Herpes Simplex Viruses

HSV is a neurotropic virus, causing encephalitis in both immunocompetent and immunosuppressed patients. The virus targets structures of the mesial temporal lobe, producing symptoms including headache, fever, confusion, language and memory impairment, and, in severe cases, depressed consciousness and status epilepticus. In those who are immunosuppressed, a more indolent course may present due to the limited inflammatory response that can be mounted. Diagnosis is made with PCR on CSF, although false-negative CSF PCR has occurred. It is important to note that CSF pleocytosis may be absent in HIV-infected patients. Quantifying the viral load offers prognostic information: Mortality is 22% in patients who have greater than 100,000 copies/μL, whereas sequelae are mild to moderate (seizures, permanent memory impairment) in those with fewer viral copies. Neuroimaging may show edema and hemorrhagic necrosis in the temporal lobes and basal frontal lobes, reflecting the path of viral entry from its latent presence in the trigeminal nerve. In a retrospective analysis, immunocompromised adults had more extensive involvement of the brain with involvement of the brainstem, cerebellum, and atypical regions including scattered lesions in the cerebrum, sometimes in the absence of temporal lobe involvement. Electroencephalogram shows focal slowing, often with periodic complexes or other epileptiform discharges in the same areas. Abundant viral inclusions (Cowdry type A bodies) can be seen in patients without necrosis or hemorrhage on pathologic examination. Serum antibodies to HSV-1 are present in up to 70% of the general population and to HSV-2 in 16% to 33%. Because of this, the presence of antibodies does not help in diagnosis. Morbidity and mortality of HSV encephalitis in HIV patients remain high despite acyclovir as patients may present atypically and may have associated acyclovir resistance.

HHV-6 and *HHV-7* are important causes of encephalitis, meningitis, and myelitis in patients with AIDS that also have predilection for the temporal lobes. *HHV-8* is responsible for Kaposi sarcoma, which rarely involves the CNS.

Cytomegalovirus

CMV is typically a manifestation of severe immunocompromised state (CD4 count <50 cells/μL) and most commonly presents with retinitis and gastrointestinal symptoms but may also present with a primary neurologic syndrome including rhombencephalitis, ventriculitis, micronodular encephalitis, or polyradiculitis. CMV-associated polyradiculitis is a common neurologic presentation with rapid development of flaccid paraplegia, urinary retention, and prominent pain radiating into the lumbar and sacral root distributions. CMV encephalitis may present with subcortical diffuse white matter abnormalities and may be clinically difficult to differentiate from HIV-associated encephalopathy. A neuropathology study of HIV-infected patients reported 28 (17%) cases of CMV encephalitis, most of them with premortem diagnosis of HIV-associated cognitive decline. Neurologic infections from CMV often occur in the setting of systemic CMV infections.

Diagnostic workup should include ophthalmologic examination because 30% of patients with neurologic CMV complications present with concomitant CMV retinitis, and CSF should be tested for CMV-PCR. Treatment recommendations for neurologic CMV complications vary and include ganciclovir, foscarnet, valganciclovir, or a combination. Induction therapy is recommended for at least 2 to 4 weeks, with maintenance therapy for at least 3 to 6 months with monitoring of CSF PCR and immune reconstitution.

Human T-Lymphotropic Virus 1 and 2

HTLV is also neurotropic and a member of the same family of retroviruses as HIV. HTLV-1 causes a chronic spastic paraparesis with gradual onset and its most frequent symptoms are gait disturbance and urinary symptoms. There is conflicting evidence on whether HTLV-1 coinfection accelerates or slows HIV infection and whether HIV coinfection predisposes to clinical manifestations of tropical spastic paraparesis. Some evidence suggests HIV-1/HTLV-1 coinfection may lead to production of HIV-1 particles with expanded cell tropism and the ability to directly infect female genital epithelial cells, which normally act as an important barrier to HIV infection in females. Contrary to the conflicting evidence of HTLV-1 coinfection, it is generally accepted that HTLV-2 coinfection exerts a negative effect on HIV-1 replication by modulating the cellular microenvironment favoring its own viability and inhibiting HIV-1 progression.

Hepatitis B and C

Due to shared mode of transmission, coinfection of HIV and hepatitis B virus is common with an estimated 4 million people worldwide being coinfected. Neurologic conditions caused primarily by hepatitis B infection including peripheral neuropathy and encephalopathy related to hyperammonemia, may increase the severity of cognitive decline and peripheral neuropathy symptoms seen with primary HIV infection. HIV and hepatitis C virus (HCV) share large worldwide populations. In the United States, an estimated 25% to 40% of HIV-infected individuals are coinfected with HCV. The highest rates of coinfection are seen in those who are IV drug users. HCV alone is known to be neurotoxic. However, controversy remains regarding whether HCV coinfection worsens cognitive function in HIV-infected individuals because data to date are conflicting. This is also becoming less clinically important in the setting of newly available curative treatments for most HCV infections. HCV coinfection has been also correlated with an increased risk of primary intracranial hemorrhage, although the role for HCV coinfection in the risk of ischemic stroke is less well-defined.

Fungal Infections

Fungal infections and their treatment are discussed in detail in Chapter 67, so only those aspects important for HIV-infected patients are presented here.

Cryptococcosis

Cryptococcal infection, the most common cause of meningitis in individuals with HIV infection, was a presenting illness in 25% to 50% of AIDS patients in older clinical series. Although less common in much of the West, it remains prevalent in many regions worldwide especially sub-Saharan Africa, which accounts for approximately three-quarters of cases. The yeast is an ubiquitous environmental encapsulated fungi found in soil and bird feces and enters the body via inhalation. CNS involvement emerges from latent infection most commonly when CD4 counts fall below 100 cells/μL. Cryptococcal meningitis most commonly presents as a subacute meningitis or meningoencephalitis. Some patients demonstrate more severe symptoms such as seizures, lethargy, and coma resulting from elevated intracranial pressure. In protracted meningeal infection, small cryptococcomas can be found, and stroke may occur due to vasculitis. CT and MRI can be normal early on but show hydrocephalus and meningeal enhancement as the infection evolves. Cryptococcomas can be visualized near the ventricles and adjacent to subarachnoid spaces. CSF should be tested for cryptococcal antigen and cultured for fungus. In resource-limited settings, India ink staining is frequently used because cryptococcal antigen testing may not be available. CSF opening and closing pressure should be measured because it is elevated in the majority of patients with cryptococcal meningitis. In settings where CSF studies are unavailable, a positive serum cryptococcal antigen in a patient with a compatible clinical syndrome correlates well with CNS disease with higher titers having higher sensitivity and specificity for CNS cryptococcal infection. The principles of treatment for patients with cryptococcal meningitis include (1) antifungal therapy, (2) lowering elevated intracranial pressure, (3) initiating or optimizing antiretroviral therapy to improve immune function, and (4) management of immune reconstitution if it develops. Induction therapy includes amphotericin B plus flucytosine. A clinical trial in sub-Saharan Africa revealed equal efficacy and reduced adverse effects with a shorter (1-wk) duration of amphotericin and flucytosine therapy compared to the previous standard of 2 weeks of induction treatment. Fluconazole is the basis of maintenance therapy and must be continued until there is recovery of immune function. Patients with elevated opening pressure should undergo daily therapeutic lumbar punctures with measurement of closing pressures until pressures have normalized.

Primary prophylaxis using fluconazole or another azole may be instituted if the CD4 count falls below 200 cells/μL. Early initiation of antiretroviral therapy in the setting of cryptococcal meningitis has been shown to increase mortality, and treatment is typically delayed for 5 weeks after treatment of fungal infection.

Candidiasis

Candida is a rare cause of meningitis in severely immunosuppressed patients. Autopsies have occasionally shown *Candida* in brain parenchyma. Resistant organisms may emerge in patients who have been treated with fluconazole for primary prophylaxis.

Coccidioidomycosis

Coccidioidomycosis is endemic to the southwestern United States and certain areas of Mexico and Central and South America. Immunosuppressed patients more commonly develop disseminated infection, although rarely present with CNS involvement. Basilar meningitis is the most common presentation in those with neurologic involvement, which is typically accompanied by a reticulonodular diffuse infiltrative pneumonia. As the organism is often difficult to grow on CSF culture, presumptive diagnosis is often made through identification of *Coccidioides immitis* spherules in tissue, sputum, bronchoalveolar lavage fluid, or other body fluid. Chronic meningitis due to *C immitis* occurs in about 10% of patients from endemic areas with CD4 counts less than 200 cells/mL. The most common symptoms are headache and slowly worsening mental status changes. Symptoms are usually severe only in patients who develop endarteritis obliterans or hydrocephalus. Treatment of disseminated coccidioidomycosis includes systemic antifungal therapy with amphotericin B or azoles. Amphotericin B remains the drug of choice for life-threatening disease.

Histoplasmosis

Histoplasma capsulatum var *capsulatum* primarily affects those living in the valleys of the Ohio and Mississippi Rivers in the United States and those living in Latin America. *H capsulatum* var *duboisii* is described only in Africa and is a common endemic mycoses in HIV-infected patients. In patients with advanced HIV infection, histoplasmosis typically manifests with disseminated disease as opposed to the asymptomatic or limited pulmonary infection observed in the majority of healthy individuals exposed to *H capsulatum*. Neurologic symptoms include headache and encephalopathy with findings of a lymphocytic meningitis and focal parenchymal lesions in the brain or spinal cord.

Aspergillosis

Aspergillus fumigatus is a rare cause of brain abscess in HIV patients. *Aspergillus* is an angiotropic fungus that causes a necrotizing angiitis in the brain. Secondary thrombosis and hemorrhage can occur with the anterior and middle cerebral arteries being most commonly involved. Evolving hemorrhagic infarcts convert into septic infarcts with associated abscesses and cerebritis. Intracranial spread of *Aspergillus* infection occurs less frequently

through direct or contiguous spread. Direct extension from the sinuses or orbit has been reported causing abscess formation in the frontal lobes. Meningitis, less frequent than abscess, tends to involve the base of the brain. *Aspergillus* myelitis and invasion of the cavernous sinus have also been reported in AIDS patients. *Mucorales* can cause a similar picture, but this organism is not increased in frequency in AIDS patients.

Neuroimaging should be obtained prior to lumbar puncture to determine whether there is abscess formation. Organisms are rarely found in CSF, and surgical removal of *Aspergillus* abscesses may be the only manner of diagnosis. Amphotericin B combined with flucytosine and treatment of the source of infection is the treatment of choice.

Parasitic Infections

The geographic and patient ecologies of parasitic and HIV infections intersect in many areas including the tropical environments of sub-Saharan Africa, Central and South America, Thailand, and India, which foster the presence of malaria and other parasitic infections. Discussion in the following text focuses on the interaction of parasitic infections in HIV-infected individuals.

Toxoplasmosis

For many years, toxoplasmosis was the most common cause of brain lesions in patients with AIDS and a frequent cause of death. Today, *Toxoplasma gondii* accounts for less than 2% of AIDS deaths in the United States, although it remains a major contributor to death in HIV-infected patients worldwide. Most of this gain is due to effective antiretroviral treatment, but effective and well-tolerated drugs for both treatment and prophylaxis of toxoplasmosis infection have also contributed. Neurologic symptoms are referable to the sites of mass lesions. These most often occur at the gray-white junction and in the thalamus or basal ganglia. With multiple lesions, the clinical picture may appear nonfocal with seizures and signs of increased intracranial pressure. Meningitis, ventriculitis, and hydrocephalus have been described in the AIDS population, although they are less common presentations than focal mass lesions. Fever and headache are present in up to 70% of patients. CT and magnetic resonance scans demonstrate ring-enhancing or nodular lesions with marked surrounding edema. With MRI, lesions have decreased signal with T1-weighted sequences but increased signal on T2-weighted images (Fig. 70.3). Multiple lesions are seen in 60% of cases. Thallium brain SPECT shows decreased uptake with a toxoplasmosis abscess, which can be helpful in distinguishing CNS toxoplasmosis from primary CNS lymphoma which shows increased uptake. A radiologic and clinical response to treatment should be seen in 7 to 10 days after the initiation of treatment. If none is seen, brain biopsy should be obtained to evaluate for primary CNS lymphoma. As a result, most cases are now diagnosed by therapeutic response rather than brain biopsy. PCR for toxoplasma can be done on CSF but has a low yield, and serum toxoplasmosis IgG levels are sensitive but nonspecific for the diagnosis.

Treatment is with sulfadiazine or sulfadoxine and pyrimethamine. Folinic acid should be given to avoid vitamin B deficiency in the patient. Inadvertent substitution of folic acid will allow survival of the parasite. Patients allergic to sulfa can undergo desensitization or receive atovaquone, clindamycin plus pyrimethamine, or cotrimoxazole, which can also be used for primary prophylaxis. Concomitant corticosteroid therapy is occasionally needed due to severe edema but should be avoided whenever possible because it can interfere with the diagnosis of primary CNS lymphoma if the brain lesion does not respond to treatment as expected.

FIGURE 70.3 Fluid-attenuated inversion recovery magnetic resonance imaging **(A)** and contrast-enhanced computed tomography **(B)** in a human immunodeficiency virus-positive patient with toxoplasmosis. Extensive bilateral white matter T2 hyperintensity and multiple contrast-enhancing lesions are present.

Malaria

Malaria is widespread in many of the same areas where HIV is prevalent, although the effects of coinfection are poorly understood. Patients at highest risk for cerebral manifestations of malaria include those with a lack of acquired immunity toward *Plasmodium falciparum*. When it involves the brain, *P falciparum* infection causes seizures, including status epilepticus, cerebral edema, alteration of consciousness and coma, and signs of brainstem dysfunction. A recent meta-analysis of studies of malaria and HIV coinfection in sub-Saharan Africa suggested that coinfection was associated with an increased frequency of clinical parasitemia and severe malaria in children, pregnant women, and other adults. Treatment strategies do not differ for either infection in the setting of coinfection, but malaria prevention efforts are ultimately key in reducing the associated morbidity of this coinfection.

Trypanosomiasis

Infection by *Trypanosoma brucei gambiense* or *rhodesiense* causes sleeping sickness in Africa, and *Trypanosoma cruzi* causes Chagas disease in South America; in AIDS patients, it may rarely lead to mass lesions or meningoencephalitis.

Cysticercosis

Immunosuppression does not affect the virulence and prevalence of *T solium* infection, but neurocysticercosis should be considered in the differential of an HIV-infected patient from a region endemic for cysticerci. Lesions are most often calcified, although cysts containing live organisms in the larval state are occasionally seen. Anticonvulsant drugs are necessary to treat seizures, but antiparasitic agents, such as praziquantel and albendazole, are rarely needed.

Bacterial and Mycobacterial Infection

Syphilis

Neurosyphilis, which is caused by *T pallidum*, occurs with greater frequency in individuals coinfected with HIV. Although not an opportunistic infection, syphilitic infection behaves differently in the presence of AIDS, and genital syphilis facilitates acquiring HIV infection. About 15% of patients with primary syphilis are seropositive for HIV. Conversely, positive serology for syphilis may occur in over 35% of some HIV-infected populations. Progression from primary syphilis (painless chancre) to later stages is typically more rapid in HIV-infected patients with lower CD4 counts. Syphilis can affect many parts of the nervous system including the meninges, brain, brainstem, spinal cord, nerve roots, and cerebral and spinal blood vessels. Syndromes of early neurosyphilis are more common than late syndromes (general paresis and tabes dorsalis). Syphilitic meningitis is the earliest neurologic complication of syphilis and is caused by invasion of the meninges by the spirochete. These can sometimes lead to cerebral vasculitis and stroke, most commonly involving the middle cerebral artery. Late stages of neurosyphilis include meningovascular involvement of the medium and large vessels as well as parenchymatous disease. Parenchymatous neurosyphilis is typified by tabes dorsalis, involving the dorsal roots and posterior columns, and general paresis. More recently, neurosyphilis mimicking HSV encephalitis, temporal lobe epilepsy, and limbic encephalitis have been reported. All patients who are HIV positive and also seropositive for syphilis require an analysis of CSF to detect and treat neurosyphilis before it has permanent and disabling consequences. Although a positive CSF serology using fluorescent treponemal antibody (FTA) or Venereal Disease Research Laboratory (VDRL) is enough to initiate treatment, the CSF in neurosyphilis also usually contains white cells (usually mononuclear) and may also have increased protein. CSF VDRL, however, may be negative. Treatment with IV penicillin or 4 weeks of doxycycline or minocycline should be continued until there is a fourfold drop in serum titers. Ceftriaxone has a 23% failure rate, so its use is not recommended. HIV patients should have serology tested monthly for 3 months and at 3-month intervals thereafter. Lumbar puncture should be repeated after 6 months to assure an adequate response to treatment. If serologic titers remain stable or rise, retreatment is indicated. Complete normalization of CSF VDRL reactivity is less likely in those with higher baseline values and peripheral blood CD4 counts less than 200 cells/μL.

Mycobacteria

Mycobacterium avium-intracellulare: *Mycobacterium avium-intracellulare* was one of the earliest opportunistic infections described in patients with AIDS, although neurologic involvement was usually detected only at autopsy. The organism has been responsible for cases of immune reconstitution syndrome when antiviral treatment is started. Patients with disseminated *M avium-intracellulare* may develop meningoencephalitis, cranial neuropathies, and epidural abscess, but defining neurologic syndromes due to *M avium-intracellulare* has been difficult due to coinfection with several opportunistic organisms.

Mycobacterium tuberculosis: Worldwide, over 14 million people are coinfected with TB and HIV. In 2012, an estimated 1.3 million died of TB, including 320,000 coinfected with HIV. Tuberculous meningitis (TBM), which is the most deadly form of the disease, is 5 times more frequent in HIV-infected individuals. The elevated risk of TB in HIV-infected persons is due in part to impairment of T cell–mediated immunity, with TB risk increasing as CD4 cell count declines. In addition, the Beijing strain of TB, which has particularly high virulence, is associated with HIV infection and multidrug resistance.

CNS manifestations of TB occur from hematogenous dissemination of the bacteria from primary lung involvement with formation of small subpial and subependymal foci. In HIV-infected individuals, clinical presentation is typically similar to those who are HIV negative, although those who have very low CD4 counts can present atypically with more disseminated disease and altered consciousness. The most common presentation is meningitis, which is frequently a subacute or chronic presentation, followed by tuberculomas. Meningitis preferentially involves the basilar meninges and is associated with hydrocephalus, multiple cranial neuropathies, and ischemic stroke. TB may also present with spine disease, affecting the vertebral bodies (Pott disease) or the spinal cord. Diagnosis can be particularly challenging as the clinical picture often mimics other opportunistic infections, including cryptococcal meningitis. CSF may show an early neutrophilic response followed by lymphocytic predominance, low glucose, and elevated protein, although studies have shown that there is a reduced CSF white blood cell count in HIV-infected adults not receiving cART compared to HIV-uninfected adults. CSF protein has also been noted to be normal in HIV-positive patients. When cultured from CSF, the organism takes 3 to 4 weeks to grow and can be difficult to detect. Acid-fast bacillus (AFB) can also be detected by PCR, although the sensitivity is low. Although the PCR-based CSF GeneXpert test

shows improved sensitivity compared to other diagnostics for TBM and a faster turnaround time than culture, it has not been shown to reduce mortality in high-TB burden settings and has less than optimal sensitivity. Treatment for TBM is extrapolated from clinical trials for pulmonary TB and includes rifampicin, isoniazid, pyrazinamide, and streptomycin (or ethambutol) for intensive phase, followed by rifampicin and isoniazid for maintenance along with adjunctive corticosteroids. Recent studies have shown that high-dose rifampicin and a fluoroquinolone early in treatment may decrease mortality. It is important to note that there is an increased risk for drug resistance to isoniazid and rifampicin in HIV-positive patients with TB, causing further challenges to treatment. For those who are cART naive, delay in treatment initiation for up to 2 months is recommended because studies suggest this reduces the rate of life-threatening adverse events but does not alter overall mortality.

Neoplasms

Lymphoma incidence has declined markedly, from a range of 0.6% to 3% of patients in pre-cART clinical series to rare or no occurrence in post-cART series. Clinical signs are nonspecific and include focal neurologic signs, seizures, cranial neuropathy, and headache. CT may be normal or show hypodense lesions as well as single or multiple lesions with patchy or nodular enhancement. Thallium SPECT shows increased uptake in lymphoma, which aids in distinguishing it from toxoplasmosis which shows decreased uptake. Epstein-Barr virus DNA is found in PCR studies of CSF but is not predictive of the diagnosis. Brain biopsy is required for diagnosis. Response to therapy with radiation and chemotherapy (especially high-dose methotrexate in combination with cART) is improved by current antiretroviral regimens, with longer survivals and reports of complete tumor regression, although this is rare. Opportunistic infections may coexist with tumor and should be excluded by appropriate studies.

Other neoplasms reported rarely in AIDS patients include metastatic Kaposi sarcoma (associated with HHV-8) and primary glial tumors, but their incidence has also been dramatically decreased by cART. Non–AIDS-defining malignancies are now more important in the treated HIV population and occur with increased frequency compared with the uninfected population. An elevated risk is reported for the following cancers: anal, vaginal, Hodgkin lymphoma, liver, lung, melanoma, oropharyngeal, leukemia, colorectal, and renal. Routine cancer screening and smoking cessation are therefore important in this population.

Nutritional and Metabolic Consequences

Nutritional deficiency may result from inadequate amounts of thiamine, vitamin B_{12}, folic acid, and glutathione, which in turn may cause encephalopathy, dementia, neuropathy, or spinal cord disorders. Metabolic abnormalities often occur in late-stage disease and are reversible causes of encephalopathy. Testosterone deficiency is increasingly recognized in long survivors and may contribute to encephalopathy.

MANAGEMENT

cART has transformed the course of AIDS from a fatal disease to a chronic illness. Even before cART, prophylactic treatment of common opportunistic infections had reduced AIDS deaths. Improved medical care has also reduced the need for hospital admissions in this population.

Antiretroviral drugs improve morbidity due to HIV and extend survival. More than 40 drugs in seven classes, including combination drugs, have been approved for use, and more are in clinical trials or development (Table 70.8). New drugs are in development that target various phases of the viral cycle and include attachment inhibitors and chemokine receptor inhibitors.

Current recommendations regarding initiation of cART include starting antiretroviral therapy for all HIV+ patients regardless of CD4 count, a strategy known as *test and treat*. Deliberately delaying initiation of antiviral treatment (eg, until a particular CD4 threshold) contributes to non-AIDS events, such as cardiovascular, renal, and hepatic disease, that can occur as a result of an infection's ongoing inflammatory effects and is associated with higher mortality.

Adverse Neurologic Effects of Drug Treatment for HIV Infection

The most important adverse effect of initiation of cART in an immunosuppressed patient is immune reconstitution syndromes.

Vaccination of patients with HIV infection (or their household contacts) is considered worth the risk if the percentage of CD4 lymphocytes is above 15% in children or greater than 200 cells/μL. With varicella vaccine, clinicians should be prepared to use acyclovir if symptoms of varicella infection develop. Measles vaccine has rarely led to subacute sclerosing panencephalitis. Other antimicrobials used for prevention or maintenance therapy of fungal and parasitic infections can have neurologic side effects, such as testosterone deficiency with azole use, neuropathy with isoniazid if supplemental vitamin B_6 is not given, and seizures from ganciclovir. Increased sensitivity to psychotropic drugs leading to prominent extrapyramidal effects is seen in AIDS patients. Because new medications with different mechanisms of action are introduced, it is important that any adverse effects be reported using systems like the U.S. Food and Drug Administration's Sentinel Initiative to detect trends that will allow practitioners to best balance risks and benefits in treating HIV infection.

Table 70.8 lists medications in current use by class, with neurologic toxicities. The following is a brief summary of the most important toxicities.

Zidovudine causes a mitochondrial myopathy with ragged red fibers with muscle energy failure. Severe anemia (which can be corrected using erythropoietin growth factor) also contributes to fatigue.

The "D-drugs," didanosine (ddI), zalcitabine (ddC), and stavudine (d4T), cause a sensory neuropathy that is often painful and sometimes difficult to distinguish from the neuropathy caused by HIV itself. D-drugs are now rarely used because of the risk of sensory neuropathy.

Efavirenz, a nonnucleoside reverse transcriptase inhibitor, causes sleep disruption, psychiatric symptoms, and nightmares that can lead to its discontinuation by patients.

Protease inhibitors such as ritonavir and nelfinavir cause lipodystrophy. The cosmetic consequences often result in patients avoiding these drugs. The associated metabolic syndrome contributes to higher rates (16% per year) of myocardial infarction and stroke in long-term users. Some protease inhibitors, including indinavir, saquinavir, and ritonavir, are also associated with neuropathy, probably resulting from effects on dorsal root ganglia.

TABLE 70.8 Categories of Drugs Used to Treat Human Immunodeficiency Virus

Name	Former Name	Brand Name	Side Effect	Year Introduced
Nucleoside Reverse Transcriptase Inhibitors				
Abacavir		Ziagen	Cognitive, myopathy, seizures	1998
Didanosine	DDI	Videx	Neuropathy, myopathy	1991
Lamivudine	3TC	Epivir	Neuropathy, lactic acidosis	1995
Stavudine[a]	d4T	Zerit	Neuropathy, myopathy	1994
Zalcitabine[a]	ddC	Hivid	Neuropathy	1992
Zidovudine	AZT	Retrovir	Neuropathy, myopathy, cognitive, seizures	1987
Nucleotide Reverse Transcriptase Inhibitors				
Emtricitabine	FTC	Emtriva	Lactic acidosis	2003
Tenofovir disoproxil fumarate		Viread	Encephalopathy	2001
Nonnucleoside Reverse Transcriptase Inhibitors				
Delavirdine		Rescriptor	Rash	1997
Efavirenz		Sustiva	Cognitive, insomnia, hallucinations	1998
Etravirine		Intelence	Rash	2008
Nevirapine		Viramune	Hepatotoxicity, rash	1996
Rilpivirine		Edurant	Hepatotoxicity, rash	2011
Protease Inhibitors				
Amprenavir[a]		Agenerase	Lipodystrophy, metabolic syndrome, myopathy (if combined with statins)	1999
Atazanavir		Reyataz	Same as Amprenavir	2003
Darunavir		Prezista	Same	2006
Fosamprenavir		Lexiva	Same	2007
Indinavir[a]		Crixivan	Same plus neuropathy	1996
Nelfinavir		Viracept	Same plus visual symptoms	1997
Ritonavir		Norvir	Same plus neuropathy and visual symptoms	1996
Saquinavir		Invirase	Same plus neuropathy	1995
Tipranavir		Aptivus	Same plus neuropathy	2006
Integrase Inhibitors				
Raltegravir		Isentress	Muscle necrosis	2007
Dolutegravir		Tivicay	Hepatotoxicity, rash	2013
Entry Inhibitors				
Maraviroc		Selzentry	Hepatotoxicity, rash	2008
Fusion Inhibitors				
Enfuvirtide		Fuzeon	Sleep disruption	2007
Pharmacokinetic Enhancers				
Cobicistat		Tybost	Renal toxicity	2014
Combination Drugs				
Lamivudine/zidovudine		Combivir	See above	1997
Abacavir/lamivudine		Epzicom	See above	2005
Abacavir/lamivudine/zidovudine		Trizivir	See above	2000
Emtricitabine/tenofovir		Truvada	Lactic acidosis	2004
Emtricitabine/tenofovir/efavirenz		Atripla	Insomnia, hallucinations	2006
Lopinavir/ritonavir		Kaletra	Same as above	2000
Emtricitabine/rilpivirine/tenofovir		Complera	See above	2011
Elvitegravir/cobicistat/emtricitabine/tenofovir		Stribild	See above	2012
Elvitegravir/cobicistat/emtricitabine/tenofovir alafenamide		Genvoya	See above	2015
Abacavir/dolutegravir/lamivudine		Triumeq	See above	2014
Emtricitabine/rilpivirine/tenofovir alafenamide		Odefsey	See above	2016
Bictegravir/emtricitabine/tenofovir alafenamide		Biktarvy	See above	2018

[a]Rarely used in the United States.

Muscle necrosis with myoglobinuria has been reported with raltegravir, an integrase inhibitor. Lactic acidosis is associated with some nucleoside reverse transcriptase inhibitors.

Precautions for Clinical and Laboratory Services

Strict observation of contamination management procedures or universal precautions is mandatory. Hospital patients with known or suspected HIV infection are not isolated unless they have respiratory infection, such as TB, or severe neutropenia. Strict precautions should be observed in handling all waste, body fluids, and surgical specimens. Gloves must be worn to prevent skin and mucocutaneous contact with blood, excretions, secretions, and tissues of infected patients. Goggles or glasses should be used if heavy aerosol contamination with blood or other secretions is anticipated (eg, in the operating room). Masks are not needed unless the patient requires respiratory isolation for other reasons. Needles and other sharp instruments in contact with infected blood should be disposed of in proper safety containers. Health care workers should not recap needles to avoid needlestick injury.

The risks to health care workers are small but real. HIV seroconversion has been documented following needlestick injury or mucocutaneous exposure. The converse risk to patients from infected workers is exceedingly small, but HIV-positive workers should not perform or assist with invasive procedures in which cuts may occur. Postexposure prophylaxis with two drugs is recommended for HIV exposure through percutaneous or mucosal routes, and with three drugs for significant blood exposure (visibly contaminated needle or device with deep penetration). HIV and hepatitis B and C serologies should be determined immediately. Problems encountered with postexposure prophylaxis include side effects of therapy, lack of efficacy, and false-positive HIV tests on rapid screening assays. Postexposure treatment is estimated to reduce HIV transmission risk by 80%.

HIV is readily inactivated by heat and standard sterilization solutions, including 70% alcohol. Special sterilization procedures may not be necessary but are often used.

OUTCOMES

People living with HIV may die of HIV infection, opportunistic infections, causes unrelated to HIV infection, or of complications related to treatment. In general, people living with HIV who are on effective cART with systemic viral suppression can have near normal life spans. With more people surviving to older ages with HIV infection, however, has come increased awareness of geriatric syndromes associated with HIV infection, including frailty, sarcopenia, and incontinence. For example, frailty is a complex geriatric syndrome, which is essentially a measure of multimorbidity characterized by decreased physiologic reserves and increased vulnerability to a variety of serious adverse health outcomes. It occurs earlier and at higher rates among people with HIV than age- and sex-match counterparts. Furthermore, many medical comorbidities common in geriatric populations tend to occur earlier—often a decade or more earlier—in people with HIV infection. This "accelerated aging" is thought to be due to low levels of chronic inflammation that persists despite effective cART and leads to early immunosenescence. As such, all people with HIV infection need rigorous evaluation for systemic and neurologic syndromes irrespective of their stage of HIV infection because of the risk for multiple, coexistent, or sequential problems, including disorders unrelated to HIV.

Great strides have been made in the medical management of HIV infection, with the prevalence of some neurologic sequelae seen with profound immunosuppression reduced. Nonetheless, HIV infection remains a serious diagnosis with common neurologic manifestations and is rapidly fatal in countries where access to effective treatment is limited. Therapy does not eliminate latent provirus and may fail if resistant mutants arise. Candidate vaccines are in clinical trials in areas of high seroprevalence and seroconversion. The complex biology of the virus and the host immunogenetic response to infection pose significant challenges to successful vaccine development. Additional strategies to "cure" HIV infection include the "shock and kill" strategy, which uses drugs to "shock" latent HIV virus into replicating, and then the active virus and cells producing the active virus would be "killed" by antiretroviral therapy, normal immune system processes, or other interventions designed to kill infected cells. Elimination of viral reservoirs, including the CNS, remains as potential problem to this strategy for "cure" and is a subject of significant active investigation.

Multiple Sclerosis and Related CNS Neuroimmune Diseases 71

Erin E. Longbrake and Sarah F. Wesley

KEY POINTS

1. Multiple sclerosis (MS) is a chronic central nervous system autoimmune disease characterized by inflammation and neurodegeneration. There are both genetic and environmental risk factors.
2. MS typically begins in young adulthood. It is the most common cause of nontraumatic neurologic disability in young people in the United States.
3. Both T and B lymphocytes are dysregulated in MS.
4. Diagnostic criteria for MS (McDonald criteria) incorporate clinical/radiologic/cerebrospinal fluid findings to establish dissemination in time and space.
5. MS may follow either a relapsing or progressive clinical course.
6. Disease activity (a clinical relapse or new/enlarging T2-weighted or gadolinium-enhancing lesions on MRI) may occur in both relapsing and progressive MS.
7. Disease progression (slow/steady worsening of neurologic dysfunction) may be punctuated by periods of stability.
8. Numerous immunomodulatory therapies are effective for treating relapsing MS, and outcomes are best when treatment is initiated early.
9. Neuromyelitis optica spectrum disorders and anti-myelin oligodendrocyte glycoprotein disease have pathologic autoantibodies and are distinct from MS.

INTRODUCTION

Multiple sclerosis (MS) is a chronic autoimmune disease. Although it remains the leading cause of nontraumatic neurologic disability in young people, the last decade has brought significant advances in understanding MS pathophysiology with new treatments and diagnostic modalities. The identification of a pathologic aquaporin 4 (AQP4) autoantibody has definitively established neuromyelitis optica spectrum disorders (NMOSD) as a distinct disease entity, where they were previously considered an MS subtype. Myelin oligodendrocyte glycoprotein (MOG) spectrum disease is another increasingly understood neuroinflammatory entity that can present with symptoms and signs overlapping with MS and NMOSD.

MULTIPLE SCLEROSIS

Introduction

MS is a chronic autoimmune disease of the CNS characterized by inflammation and neurodegeneration that develops in genetically susceptible hosts and that has a variable clinical course. MS was initially identified by Scottish pathologist Robert Carswell in 1838, but it was not until the 1860s that French physician Jean Marie Charcot at the Pitié-Salpêtrière Hospital in Paris comprehensively described and termed *MS, sclérose en plaques disseminées*. Significant advances in understanding and treating the disease have occurred in the past several decades. The natural history of MS can follow a relapsing-remitting pattern or present in a progressive manner. Diagnosis is made based on clinical history and exam as well as cerebrospinal and radiographic characteristics. Individual differences in prognosis depend on a combination of genetic and environmental factors as well as access to early effective immunotherapy.

Epidemiology

The prevalence rate of MS in the United States has been estimated around 309 per 100,000, with a prevalence varying depending on latitude, which is discussed in detail later in this chapter. It is a leading cause of nontraumatic disability in young adults. The median age of onset is 23 to 24 years, with the first symptoms rarely occurring before the age of 10 or after the age of 60. Women are affected approximately twice as often as men except in individuals with the primary progressive form of the disease where there is no gender discrepancy.

Pathobiology

Immunobiology

MS is considered an autoimmune disease that results from a complex interplay of genetic and environmental factors. Ultimately, MS develops when proinflammatory, myelin-reactive or more recently identified β-synuclein T cells target the CNS. B cells are also involved in disease pathogenesis, presumably as antigen-presenting cells, evidenced by the success of B-cell

depleting immunotherapies, but the mechanisms by which they influence disease are still being elucidated.

The immune system is dysregulated in MS patients at many levels. The initial loss of self-tolerance may occur when genetically susceptible individuals develop an immune response against pathogenic epitopes that share antigen cross-reactivity to myelin peptides. Antigen-presenting cells then present relevant self-antigens to peripheral $CXCR3^+CD4^+$ T cells, leading to their activation and the subsequent generation of autoreactive proinflammatory T-helper (Th) 1 and 17 subsets. B cells and monocytes are also activated. These autoreactive T cells interact with adhesion molecules on the endothelial surface of CNS venules and, with antibodies and monocytes, cross the disrupted blood–brain barrier with the aid of proteases (eg, matrix metalloproteinases) and chemokines. Within the CNS, target antigens are recognized, T cells are reactivated, and the immune response is amplified. Proinflammatory T-helper cells proliferate, and B cells mature to antibody-secreting plasma cells, whereas monocytes become activated macrophages. Together, these immune cells produce inflammatory cytokines (eg, interleukin [IL]-12, IL-23, interferon γ, tumor necrosis factor-α), proteases, free radicals, antibodies, nitric oxide, glutamate, and other stressors that collectively lead to damage of myelin and oligodendrocytes.

Depending on the location and extent of damage, demyelination may impair or block nerve conduction and result in neurologic symptoms. These may be transient or permanent. Spontaneous improvement of symptoms is attributed to resolution of inflammation, adaptive mechanisms (eg, reorganization of sodium channels), or remyelination. In contrast, loss of trophic support from oligodendrocytes causes axon degeneration and irreversible neurologic deficits.

The older classification of autoimmune diseases as being either T cell or B cell mediated has been replaced by the realization that the genetic variants leading to lower threshold of immune activation involves CD4, CD8, and regulatory T cells (Tregs) along with B cells. The dramatic clinical success of B-cell depleting therapies along with the intrathecal production of immunoglobulin in most MS patients, histologic identification of myelin-specific antibodies and antibody-associated demyelination in some MS lesions, and the discovery of ectopic lymphoid tissue containing B cells in the meninges provides strong evidence of a critical role of B cells triggering T cells in patients with MS. Pathologic studies have shown that B-cell clones are shared between the meninges and parenchyma of individual MS patients. B cells may act as antigen-presenting cells to autoreactive T lymphocyte cells. B cells may also directly produce proinflammatory cytokines, such as IL-6.

Pathology

The pathologic hallmark of MS is circumscribed demyelination that occurs in white and gray matter (Fig. 71.1A), most frequently in the periventricular white matter, juxtacortical white matter, brainstem, cerebellum, cortex, and spinal cord. White matter lesions are formed through an inflammatory process involving infiltration with macrophages, and to a lesser degree, lymphocytes. The histologic features of acute lesions include hypercellularity caused by macrophages and hypertrophic astrocytes, intense infiltration of perivascular spaces with lymphocytes and monocytes (Fig. 71.1B), and loss of myelin with relative preservation of axons (Fig. 71.1C). Acute lesions may evolve into chronic active (also mixed active/inactive) lesions, a state in which they can persist for many years. These lesions display smoldering inflammation with minor demyelinating activity at the lesion rim, and

FIGURE 71.1 **A:** Coronal section of a patient with chronic multiple sclerosis, stained with Luxol fast blue. The section shows several white matter lesions, some of which have partial remyelination (shadow plaques, asterisks). In addition, there is widespread cortical demyelination, particularly of the temporal lobes, with preservation of cortical myelin in the parietal lobes. **B:** Perivascular cuff within a demyelinating lesion consisting of mononuclear cells, including lymphocytes, monocytes, and plasma cells (hematoxylin & eosin). **C:** Lesion edge showing reduced axonal density in the lesion (left half of picture) compared to the adjacent white matter (Bodian silver staining). Axons are relatively preserved compared to the complete loss of myelin. **D:** Recently demyelinating lesion with numerous CD68-positive macrophages at the lesion edge and smaller macrophages containing processed myelin within the lesion center (CD68, brown; hematoxylin). **E:** Multiplexed immunofluorescence imaging of the same lesion as in **D**, labeled with antibodies against proteolipid protein (myelin marker, red), glial fibrillary acidic protein (astrocyte marker, green), vimentin (astrocyte marker, cyan), Iba1 (microglial marker, magenta), CD68 (macrophage marker, white) and Hoechst (nuclear marker, blue). The image shows a section of the lesion rim with macrophages, reactive astrocytes, and intact myelin in the upper part of the picture.

a hypocellular lesion center with denuded axons and astroglial scar tissue. Chronic, silent lesions consist of astroglial scar tissue without inflammation. Compared to white matter lesions, cortical demyelination is characterized by relatively minor inflammatory activity and typically associated with meningeal inflammation.

Genetic Risk Factors

Data from the haplotype map (HapMap) project has been pivotal to the understanding of the genetics of MS, with genome-wide association studies using single nucleotide polymorphisms providing an unbiased and widespread approach to scanning the whole genome and identifying haplotypes associated with risk of developing human diseases. Recent work has identified approximately half of the genetic susceptibility for risk of developing MS. Of interest, MS shares allelic variants with other autoimmune diseases, meaning that there are likely shared pathways of immune system regulation. Twin studies also show that there is a genetic risk for MS, with a monozygotic concordance rate of 30% versus a dizygotic rate of 5%. Approximately 15% to 20% of people with MS have a family history of MS. When both parents are affected, there is at least a 9% risk to their offspring of developing MS. It has been understood for some time that MS is associated with the major histocompatibility complex haplotype containing human leukocyte antigen (HLA)-DRB1*1501. Genome-wide association studies in patients with MS and other autoimmune diseases identified 233 additional autosomal susceptibility variants outside the major histocompatibility complex associated with MS risk.

Environmental Influences

Multiple environmental factors might influence the risk of MS. In general, there is a latitudinal gradient with an increased prevalence of MS further from the equator in both hemispheres. However, several regions with similar latitude have vastly different MS prevalence rates, which in some instances can be accounted for by differences in ethnic susceptibility. Western Europe and North America have the highest prevalence of MS, whereas Asia, the Middle East, and Africa have the lowest prevalence. Further evidence of an environmental effect comes from migration studies. In general, immigrants who move from one area to another before the age of 15 years acquire the MS risk associated with the new region.

Vitamin D deficiency has emerged as a risk factor for MS. The active form of vitamin D, 1,25-dihydroxyvitamin D_3, has immunomodulatory properties and can prevent or ameliorate experimental autoimmune encephalitis (EAE; a mouse model of MS). Numerous studies found an inverse correlation between sunlight exposure (the most common source of vitamin D) or dietary intake of vitamin D and the risk of MS. Indeed, the relationship to sunlight exposure may help explain the latitudinal variation of MS prevalence. A study of U.S. military personnel found that higher serum levels of 25-hydroxyvitamin D_3 were associated with a lower risk of MS. Similar findings in the Netherlands were reported, but only in women, as well as a negative correlation between 25-hydroxyvitamin D_3 levels and disability. However, it is not known whether vitamin D supplementation modifies the disease in people already diagnosed with MS. It has also been found that a highly conserved vitamin D–responsive element exists in the promoter region of the HLA-DRB*1501 haplotype, which could indicate that people with this risk allele might experience a beneficial effect from vitamin D supplementation.

Among the possible infectious causes, the case for Epstein-Barr virus (EBV) has long been of interest. The frequency of MS is low in people who are seronegative for EBV, and the risk of MS is increased in those who have had infectious mononucleosis. Moreover, over 99% of people with MS have had prior exposure to EBV, compared to 90% in the general population. The evidence for other microbial agents is less compelling, but it is possible that a number of viruses or bacteria might act as a nonspecific trigger of MS in genetically susceptible individuals.

The role of diet has also been investigated, with particular focus on whether high salt or fat intake impacts MS risk. High-salt diets increase the severity of EAE and facilitate the development of pathogenic IL-23–dependent T_H17 cells in vitro, which in turn leads to increased production of proinflammatory cytokines. This has been hypothesized to explain in part the increasing incidence of MS and other autoimmune diseases in countries consuming a "Western diet." Furthermore, research aimed at pediatric populations with MS found a greater risk of MS in extremely obese girls, compared to no increased risk in obese boys.

Although tobacco smoking has not been shown to be a direct environmental risk factor for developing MS, it has a major effect on disease severity and course. Smoking is associated with increased rates of progression and a higher risk of having the primary progressive subtype of MS. Smokers also have a faster rate of progression from relapsing-remitting MS (RRMS) to secondary progressive MS (SPMS).

Emerging work on the gut microbiome suggests that symbiotic bacteria may plan an important role in bridging environmental risk factors and immune changes. Gut bacteria and their byproducts play an important role in shaping the function of the immune system, and the composition of the gut flora is dysregulated in MS. Cross-sectional studies of MS patients have demonstrated a similar level of species richness among MS patients and healthy individuals, but underlying differences in the bacterial community structure have been consistently observed. Germ-free mice developed more severe EAE after colonization with gut microbes harvested from MS patients. The mechanisms by which the gut microbiota impact MS are still being elucidated.

Diagnosis

Disease Course

The course of MS is determined clinically. There are no biologic markers or magnetic resonance imaging (MRI) features that objectively separate the disease phenotypes, and the current classification system is based on consensus. Accurate classification is imperative for appropriate treatment with the disease-modifying drugs.

Broadly, MS cases are classified as having a relapsing or progressive phenotype. Additional characterization is achieved by incorporating the modifiers "disease activity" and "disease progression." Disease activity is manifested by clinical relapses or by the presence of new gadolinium-enhancing or incontrovertibly enlarging T2 lesions on MRI scans. Disease activity provides evidence of ongoing inflammation. An asymptomatic individual with relapsing MS and gadolinium-enhancing lesions on MRI therefore has relapsing disease with evidence of disease activity. An individual with progressive MS and gadolinium-enhancing lesions would likewise be characterized as demonstrating "active" disease. In contrast, disease progression refers to accumulation of neurologic disability, independent of relapses, in persons with an overall progressive disease course. Disease progression in MS does not take place at a steady rate, and thus, persons with progressive MS frequently remain relatively stable for long periods of time (Fig. 71.2).

Disease activity and disease progression likely have unique pathophysiologies. Disease activity is attributed to localized inflammation and influx of infiltrating immune cells. Disease progression,

FIGURE 71.2 Multiple sclerosis (MS) can be described as either relapsing or progressive. Either subtype may also exhibit *disease activity* and patients with progressive disease may exhibit either clinical stability or *disease progression*. Radiologically isolated syndromes are identified when suggestive brain lesions are observed in the absence of a clinical event *(line 1)*. Clinically isolated syndromes *(line 2)* occur when patients present with a single clinical event, but dissemination in time and space cannot be demonstrated. Relapsing-remitting MS (RRMS) is the most common clinical phenotype, occurring in approximately 85% of patients at the time of diagnosis. Patients with RRMS may exhibit disease activity in the form of relapses *(solid lines)* or new/enlarging T2 or gadolinium-enhancing lesions on magnetic resonance imaging (MRI) *(asterisks)*. *Lines 3* and *4* show that disease is labeled as RRMS irrespective of whether recovery from relapses is complete *(line 3)* or incomplete *(line 4)*, as long as a stable baseline is reestablished. Many patients eventually follow a secondary progressive MS (SPMS) pattern (*lines 5* and *6*). Patients with SPMS may still exhibit disease activity in the form of relapses or new MRI lesions, as long as the disease is slowly worsening over time. Approximately 10% to 15% of patients have primary progressive MS (*lines 7* and *8*). These patients do not have clinical relapses but may have disease activity identified with MRI. Patients with progressive MS may experience periodic plateaus, where no disease progression is observed *(line 6)*. *Solid lines* represent clinical phenotype. *Asterisks* represent new/enlarging T2 lesions or gadolinium enhancing lesions on MRI.

however, most likely represents sequelae of chronic, low-grade inflammation that is trapped behind the blood–brain barrier. Chronically activated glial cells and collections of lymphocytes in meningeal tertiary lymphoid organs may contribute to neurodegeneration and disease progression.

The diagnosis of MS requires clinical symptoms and the demonstration of lesions disseminated in time and space (see discussion in the following text). Brain lesions highly suggestive of MS may be identified in asymptomatic individuals who have undergone brain MRI for an unrelated reason (often headaches or after a motor vehicle accident). In the absence of clinical symptoms, a diagnosis of MS cannot be made, and these individuals are diagnosed with a *radiologically isolated syndrome* (RIS). This likely represents a preclinical stage of disease, and it can be argued that if spinal fluid examination reveals inflammation then it is not unreasonable to attempt short-term immunotherapy in an attempt to prevent clinical disease. There is as yet no evidence that this approach will change outcomes; however, virtually every MS study to date has found that early treatment is associated with improved prognosis. Several large clinical trials testing the efficacy of immunomodulatory therapy in patients with RIS are underway. Approximately two-thirds of individuals with RIS develop additional brain lesions within 5 years, and one-third develop a clinical event concerning for MS during that timeframe.

The next point on the MS continuum is the *clinically isolated syndrome* (CIS). This is diagnosed when an individual experiences one typical demyelinating event, such as optic neuritis or transverse myelitis, and the brain MRI is suggestive of MS but there is insufficient evidence to demonstrate dissemination in time. Patients with CIS frequently go on to develop MS; the 2-year probability of conversion to definite MS is approximately 57%. Initiation of effective disease-modifying therapy should be recommended at this stage. Modern diagnostic criteria for MS (McDonald 2017 criteria) have decreased the frequency with which CIS is diagnosed because a larger proportion of patients can be diagnosed with definite MS at the time of presentation due to imaging or spinal fluid characteristics.

RRMS is the initial form of the disease in 85% to 90% of patients. It is characterized by acute relapses interspersed with clinical remissions, as previously discussed. Symptoms from a relapse typically evolve over several days to a week before reaching a nadir. Recovery is variable, but approximately 40% of relapses result in persistent neurologic deficits and patients may accumulate disability in a stepwise fashion as a result of recurrent relapses. When left untreated, most patients with RRMS ultimately enter the *secondary progressive* phase of MS (SPMS), which is characterized by an overall phenotype of gradual deterioration (disease progression) with or without superimposed disease activity.

Primary progressive MS (PPMS) patients make up 10% to 15% of individuals with the disease. PPMS is characterized by disease progression from the time of onset (eg, a slowly progressive monoparesis). There may be plateaus and minor fluctuations, but clinical relapses never occur in PPMS. A subset of these patients may, however, exhibit disease activity in the form of new gadolinium-enhancing brain lesions or new T2 lesions on MRI.

The *Marburg variant* of MS is a rare, fulminant, and usually monophasic illness that typically results in death within 1 year. It is characterized by extensive acute demyelination manifested by tumefactive appearance, mass effect, and widespread gadolinium enhancement on MRI scans.

Clinical Manifestations

MS typically presents with a relapse or an episode of neurologic dysfunction localizable to the brain, spine, or optic nerve. Common presentations include optic neuritis, transverse myelitis, weakness, numbness/tingling, or cerebellar signs (**Table 71.1**).

Although the manifestations of MS are many and varied, a handful of clinical syndromes are strongly associated with the disease. These include acute optic neuritis, brainstem syndromes, and transverse myelitis. Lhermitte phenomenon and Uhthoff phenomenon are also frequently associated with MS.

TABLE 71.1 Classic Signs and Symptoms of Relapsing Multiple Sclerosis

Symptom	Sign	Localization
Blurred vision	Relative afferent pupillary defect Optic disc pallor Papillitis Red desaturation[a]	Optic nerve
Diplopia	Nystagmus Internuclear ophthalmoplegia One-and-a-half syndrome[b]	III, IV, and VI nerve nuclei and outflow tracts MLF PPRF
Vibratory or electrical sensation with neck flexion ("Lhermitte phenomenon")	Elicitation with neck flexion	Cervical spine, posterior columns
Tonic spasms (sometimes called *paroxysmal dystonia*)	Brief, stereotyped, often painful, unilateral muscle contractions lasting seconds to minutes May involve limbs or manifest as paroxysmal dysarthria or facial spasms	Corticospinal tracts
Pseudobulbar affect	Laughing or crying uncontrollably without emotional congruence with the displayed affect	Brainstem, also frontal and parietal subcortical white matter
Recrudescence of old neurologic symptoms with warmer temperatures ("Uhthoff phenomenon")	None	Hypothesized to be due to heat-linked blockade of partially demyelinated axons

Abbreviations: MLF, medial longitudinal fasciculus; PPRF, paramedian pontine reticular formation.
[a]Red desaturation: decreased ability to perceive the color red.
[b]One-and-a-half syndrome: eye movement abnormality including a conjugate horizontal gaze palsy in one direction and an intranuclear ophthalmoplegia in the other.

Acute Optic Neuritis

Acute optic neuritis is one of the most common manifestations of MS. Patients typically note unilateral visual loss that evolves over a few days and is preceded or accompanied by orbital pain that occurs with or is exacerbated by eye movement. On physical examination, patients with acute optic neuritis invariably exhibit a relative afferent pupillary defect, unless there is a prior history of or current optic neuritis in the opposite eye. Patients also typically exhibit color vision loss (dyschromatopsia), with red hues being lost first. Visual field defects are common, prototypically a central scotoma, but almost all types of visual field defects may be seen. Vision loss ranges from mild to severe; visual acuity of 20/200 or worse develops in about one-third of patients. The absence of a relative afferent pupillary defect in a person with acute visual loss raises the possibility of uveitis, which occurs with increased frequency in MS, although it is not directly caused by the disease. Fundoscopy in acute optic neuritis is often normal, but swelling of the optic disc may be observed in up to a third of patients. Retinal hemorrhages and exudates are uncommon.

Spontaneous recovery of vision usually occurs within the first month, even when visual loss is severe. Lack of improvement suggests an alternative diagnosis because 98% of optic neuritis patients with visual acuity 20/50 or worse improve by at least three lines on a Snellen letter chart within 6 months after the onset of symptoms. Optic atrophy, noted as pallor on funduscopic exam, is frequently found after the acute episode resolves. Progressive visual failure over years is uncommon.

Brainstem Syndromes

Oculomotor abnormalities are common in MS. Patients may exhibit diplopia, usually attributable to a sixth nerve palsy, or internuclear ophthalmoplegia. Intranuclear ophthalmoplegia, caused by lesions in the medial longitudinal fasciculus, can be recognized by impaired adduction of the affected eye with associated nystagmus with abduction of the contralateral eye. Gaze-evoked or pendular nystagmus is also common. Less commonly, smooth pursuit and saccadic eye movement abnormalities may be observed. Third or fourth nerve palsies, the one-and-a-half syndrome (reflecting damage to the parapontine reticular formation or the sixth nerve nucleus causing ipsilateral gaze palsy as well as impaired adduction in contralateral gaze due to damage to the medial longitudinal fasciculus), opsoclonus, and symptomatic homonymous field defects are rare.

Facial sensory deficits (eg, numbness or trigeminal neuralgia) and weakness may develop. Facial weakness typically follows an upper motor neuron pattern, although inflammatory demyelination involving the facial nucleus can mimic an idiopathic Bell palsy.

Vertigo can occur and may be difficult to distinguish from peripheral vestibular dysfunction. Sudden hearing loss is uncommon and should raise the possibility of an alternative diagnosis (eg, Susac syndrome). Intractable hiccups are rare but may result from lesions in the medulla or upper cervical spine. However, the occurrence of intractable nausea/vomiting and hiccups should precipitate concern for neuromyelitis optica rather than MS. Dysphagia, particularly with liquids, may develop in advanced MS.

Pyramidal Signs/Symptoms

Approximately 70% of patients exhibit spasticity, most often in the legs and accompanied by painful spasms. Spasticity can impair mobility and activities of daily living and disrupts sleep. In nonambulatory patients, it may interfere with transfers and personal hygiene. In some instances, however, spasticity of the leg extensors permits weight bearing and actually improves gait.

Patients with MS also frequently exhibit other pyramidal signs, including weakness in an upper motor neuron pattern and hyperreflexia.

Sensory Signs/Symptoms

Paresthesias, dysesthesias, and allodynia are common initial manifestations of MS and occur in most patients at some point during their disease. On physical examination, vibratory and proprioceptive loss is commonly observed. This sensory loss often contributes to gait disturbances and falls.

Lhermitte phenomenon refers to an electric sensation, which shoots down the body in response to neck flexion. It is caused by stretching of nerve fibers passing through a lesion in the cervical spine. Lhermitte phenomenon is common in MS patients with

C-spine disease, although it can also occur in individuals with other types of C-spine pathology.

Cerebellar Signs/Symptoms

An action tremor of the arms is common in MS patients. This is often accompanied by other signs of cerebellar disease, including gait ataxia, dysmetria, dysdiadochokinesia, and dysarthria. Tremor of the head, trunk, and legs is less frequent. Incapacitating tremor, scanning speech, and truncal ataxia are seen in advanced disease. Cerebellar symptoms, when present, can be severely disabling among MS patients.

Transverse Myelitis

Transverse myelitis refers to inflammation of the spinal cord. This is most often seen in the cervical and thoracic spine. It manifests clinically with numbness and weakness, with the affected limbs depending on the location of the lesion. In some cases, bladder and bowel dysfunction can manifest. Transverse myelitis has a broad differential diagnosis, including MS, neuromyelitis optica, infectious or parainfectious, nutritional deficiency, manifestations of a systemic rheumatologic disease, or may be idiopathic. The emergence of transverse myelitis warrants a thorough workup for its etiology, including evaluation for underlying demyelinating disease.

Uhthoff Phenomenon

Temporary worsening of vision with physical activity was originally described by Uhthoff in 1890. Uhthoff phenomenon now refers to new or worsening neurologic symptoms that occur in association with elevations in temperature (often during exercise or a hot shower). Symptoms are transient and attributed to reversible conduction block along demyelinated nerve fibers. The presence of Uhthoff phenomenon does not represent an MS relapse or provide evidence for ongoing neurologic damage. Indeed, whereas for some patients Uhthoff phenomenon may limit day-to-day activities, many other patients are not sensitive to heat, and accordingly, do not need to make any lifestyle adjustments.

Paroxysmal Signs/Symptoms

Paroxysmal symptoms in MS are brief, repetitive, stereotyped attacks of neurologic dysfunction that are thought to result from ephaptic spread of abnormal electrical discharges from partially demyelinated nerve fibers ("cross-talk"). These discharges can arise from areas with acute inflammation and demyelination or chronic tissue damage. The symptoms usually last a few seconds to a few minutes and may occur anywhere from a few to 200 times per day. Attacks may occur spontaneously or be provoked by sudden noises, emotion, movement, hyperventilation, or tactile stimulation. The most common paroxysmal symptoms in MS are trigeminal neuralgia and tonic spasms. Paroxysmal dysarthria, ataxia, diplopia, itching, paresthesias, pain, hemifacial spasm, and glossopharyngeal neuralgia have rarely been described.

Trigeminal neuralgia occurs in about 2% of MS patients. The character and quality of the pain is usually indistinguishable from idiopathic trigeminal neuralgia. However, trigeminal neuralgia in MS is more likely to involve both sides of the face and is often accompanied by trigeminal neuropathy or other signs of brainstem dysfunction. Trigeminal neuralgia attributable to MS is often less amenable to surgical interventions and must be managed medically.

Tonic spasms are usually stereotyped, painful attacks of unilateral dystonic posturing of the limbs. They are occasionally bilateral and rarely involve the face. The attacks last between 30 seconds and 2 minutes and can occur up to 60 times a day. Tonic spasms are probably caused by demyelinating lesions involving the corticospinal tract. However, they are not pathognomonic for MS and are occasionally seen in patients with other types of CNS pathology such as cerebral ischemia or spinal cord trauma.

Pseudobulbar affect is characterized by episodes of laughing or crying that are not congruent with the individual's emotional state. This can cause significant emotional distress to both patients and caregivers.

Bladder, Bowel, and Sexual Signs/Symptoms

Bladder dysfunction in MS encompasses both urgency and retention, or some combination of the two. It is common, affecting approximately 75% of patients. In 15%, symptoms are severe enough to prevent the patients from leaving home or attending social activities. Demyelinating lesions above the level of the pons may result in detrusor hyperreflexia with uninhibited bladder contractions, resulting in urinary urgency accompanied by frequency, nocturia, and urge incontinence. Lesions involving the reticulospinal pathways above S2 and below the pons may also lead to involuntary bladder contractions or cause simultaneous contraction of the bladder wall and urethra, a condition known as *detrusor-sphincter dyssynergia*. Patients with detrusor-sphincter dyssynergia have storage and emptying dysfunction and a combination of urgency, frequency, difficulty initiating voiding, incomplete emptying, and incontinence. Hypocontractility and failure of the bladder to empty properly occurs with demyelination of the lower sacral anterior horn cells. Complete inability to void is uncommon.

Bowel dysfunction often coexists with bladder dysfunction and is present in up to 70% of patients. It typically manifests as constipation, which may be compounded by immobility, decreased fluid intake, or medication side effects.

Sexual dysfunction is present in up to 90% of patients. The most common symptoms among men are erectile and ejaculatory dysfunction. Women have difficulties achieving orgasm, decreased vaginal lubrication, and reduced vaginal sensation. Both men and women may have reduced libido. Physiologic (eg, fatigue, weakness, spasticity, pain, hypesthesia) and psychological factors (eg, depression, anxiety about bladder and bowel dysfunction) both contribute to sexual dysfunction. Many of the medications used to treat other MS symptoms, including anticholinergics, antidepressants, and muscle relaxants, also adversely affect sexual function.

Nonspecific Multiple Sclerosis Signs/Symptoms

Fatigue is one of the most common and disabling MS symptoms, which may emerge very early. It is estimated to impact between 75% and 95% of MS patients. Indeed, fatigue (among other nonspecific symptoms) may precede the first clinical demyelinating event by months or years. Pathologic MS fatigue is out of proportion to physical activities and is typically worse late in the day. The etiology of MS-related fatigue is poorly understood.

Mood disorders are common in MS. Depression is the most common, with a lifetime prevalence of 50% before age 60 years. The etiology of depression is likely multifactorial with both psychosocial and biologic factors contributing. Among MS disease–modifying therapies, β-interferons may cause or exacerbate depression and are relatively contraindicated among patients experiencing depressive symptoms. Bipolar disorder and anxiety are also more prevalent in patients with MS than in healthy individuals.

Cognitive impairment occurs in up to 65% of MS patients and often develops early in the disease. Short-term memory, attention, concentration, verbal intelligence, visuospatial skills, and

TABLE 71.2 Multiple Sclerosis (MS) Diagnostic Criteria (McDonald 2017 Criteria)[a,b,c]

Clinical Presentation	Additional Data Required for MS Diagnosis
Two or more attacks with objective evidence of two or more lesions supported by clinical examination or MRI	None
Two or more attacks with objective clinical/MRI evidence of one lesion and reasonable historical evidence of a prior attack	None
Two or more attacks with objective evidence of one lesion on clinical examination	Dissemination in space (DIS) demonstrated by one of the following: 1. DIS on MRI[d] 2. Second clinical attack implicating a different CSF location
One attack with objective evidence of two or more lesions on clinical examination	Dissemination in time (DIT) demonstrated by one of the following: 1. DIT criteria on MRI[e] 2. Second clinical attack 3. Presence of CSF-specific oligoclonal bands
One attack with objective evidence of one lesion on clinical examination	DIS demonstrated by one of the following: 1. DIS on MRI[d] 2. Second clinical attack implicating a different DNS location *and* DIT demonstrated by one of the following: 1. DIT criteria on MRI[e] 2. Second clinical attack 3. Presence of CSF-specific oligoclonal bands
Insidious neurologic progression suggestive of MS (ie, a clinical presentation consistent with primary progressive MS)	One year of disease progression *and* two of the following: 1. DIS in brain according to 2017 McDonald criteria 2. Spinal cord MRI with two T2 lesions 3. Presence of CSF-specific oligoclonal bands

Abbreviations: CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.
[a]Note: These guidelines should be applied only to patients with a "typical" demyelinating event or clinically isolated syndrome. 2017 McDonald criteria cannot be summarily applied to patients who present with an atypical clinical phenotype.
[b]Adapted from Thompson AJ, Banwell BL, Barkhof F, et al. Diagnosis of multiple sclerosis: 2017 revisions of the McDonald criteria. *Lancet Neurol.* 2018;17(2):162-173.
[c]If all criteria are fulfilled and alternative diagnoses have been excluded, the diagnosis is MS. If there is a suspicion of MS but only some of the criteria are met, the diagnosis is "possible MS."
[d]See Table 71.3 for MRI criteria for dissemination in space.
[e]See Table 71.4 for MRI criteria for dissemination in time.

information processing are the domains most commonly affected, with slowed cognitive processing being the most common cognitive abnormality. Disturbances of language and immediate- and long-term memory occur less frequently. Cognitive impairment is not directly correlated with physical disability or disease duration. However, cognitively impaired patients have more lesions, more severe tissue damage, and smaller brain volumes than unimpaired patients as measured by conventional and nonconventional MRI techniques. In many patients, cognitive dysfunction is subtle and goes undetected in the neurologist's office. The Mini-Mental State Examination failed to identify nearly 75% of MS patients deemed to be cognitively impaired by detailed neuropsychological testing. The Symbol Digit Modalities Test, which specifically evaluates information processing speed/efficiency, has better efficacy for screening MS patients and is the single test common to all cognitive screening batteries used for this disease.

Approximately 70% of MS patients experience pain related to the disease. Pain can occur during an acute exacerbation (eg, ocular pain with optic neuritis or dysesthesias with demyelinating plaques involving spinal cord), but almost half of MS patients have chronic pain which can be severe. In addition to painful muscle spasms, paroxysmal phenomena, and the sensory symptoms discussed earlier, MS patients are more likely to have joint, muscular, and extremity pain than age- and sex-matched controls.

Diagnostic Criteria

The diagnosis of MS is established based on clinical, radiologic, and cerebrospinal fluid (CSF) criteria as well as exclusion of several mimicking etiologies. No single test result is pathognomonic of MS.

MS diagnostic criteria, referred to as the *McDonald criteria* (after the late Ian McDonald), were established in 2001 and revised in 2005, 2010, and 2017 (Table 71.2). The terminology of *dissemination in space* and *time* has been used and redefined over the course of these revisions. Dissemination in space (Tables 71.2 and 71.3) refers to the involvement of anatomically distinct locations, demonstrating a multifocal CNS process. Dissemination in time indicates that the process is chronic/multiphasic (Tables 71.2 and 71.4), as opposed to monophasic. The diagnosis of RRMS requires at least one episode of neurologic dysfunction consistent with inflammation and demyelination occurring in the absence of fever or infection and lasting at least 24 hours along with objective evidence of lesions disseminated in space and time. The diagnosis of PPMS requires at

TABLE 71.3 Magnetic Resonance Imaging Criteria for Dissemination in Space[a]

One or more T2 lesion in at least two of the following four areas:
- Periventricular
- Juxtacortical or cortical
- Infratentorial
- Spinal cord

TABLE 71.4 Magnetic Resonance Imaging (MRI) Criteria for Dissemination in Time[a]

One of the following: • One new T2 and/or contrast-enhancing lesion on any follow-up MRI • Presence of gadolinium-enhancing and nonenhancing lesions at any one time

[a]Adapted from Thompson AJ, Banwell BL, Barkhof F, et al. Diagnosis of multiple sclerosis: 2017 revisions of the McDonald criteria. *Lancet Neurol.* 2018;17(2):162-173.

least 1 year of insidious neurologic progression combined with a variety of MRI and CSF abnormalities (see Table 71.2).

MRI abnormalities may be used to demonstrate dissemination in both space and time, provided an individual has had one episode of neurologic dysfunction consistent with demyelinating disease. More recently, MS can be diagnosed in patients who have the presence of oligoclonal bands in the CSF in conjunction with a CIS and demonstration of dissemination in space. Both of these changes have allowed for an earlier diagnosis. This is of great importance because MS disease-modifying drugs seem to be most effective when given early in the disease, and a delay in treatment can result in irreversible neurologic damage.

Characteristic MS lesions are occasionally discovered on MRI in individuals with no history of neurologic symptom and a normal examination. In the absence of clinical evidence of demyelination, even if MRI abnormalities are accompanied by the presence of CSF oligoclonal bands, an elevated IgG index, and delayed visual-evoked potentials (VEPs), a diagnosis of MS cannot be established by formal criteria, and this is termed *radiologically isolated syndrome*, established in 2009 (Table 71.5). As discussed earlier, clinical trials are now in progress to determine whether short-term immunotherapy should be initiated.

TABLE 71.5 Radiologically Isolated Syndrome[a,b]

CNS white matter abnormalities meet the following criteria:
• Ovoid well circumscribed and homogeneous foci with or without involvement of corpus callosum
• T2 hyperintensities ≥3 mm^2 and meeting three of four Barkhof criteria (listed below) for dissemination in space
  • At least one gadolinium-enhancing lesion *or* at least nine T2 lesions
  • At least three periventricular lesions
  • At least one juxtacortical lesion
  • At least one infratentorial lesion
• CNS anomalies do not fit vascular pattern.

No history of remitting clinical symptoms consistent with neurologic dysfunction
MRI anomalies do not account for any clinically apparent impairments.
MRI anomalies are not related to toxic substances or a medical condition.
MRI anomalies are not better accounted for by another disease.

Abbreviations: CNS, central nervous system; MRI, magnetic resonance imaging.

[a]Note: These guidelines cannot be applied to patients with MRI phenotypes of leukoaraiosis or extensive white matter involvement without involvement of corpus callosum.

Imaging

MRIs are critical for diagnosis, disease monitoring, and treatment monitoring in MS. Brain MRI abnormalities are present in more than 95% of recently diagnosed MS patients. The MRI lesions may be clinically silent, and 5 to 10 new or enlarging gadolinium-enhancing or T2 brain lesions are identified for every clinical exacerbation in patients with relapsing MS. Spinal cord lesions are detected by MRI in 75% to 90% of those with established MS. Fifty percent to 70% of CIS patients have asymptomatic T2-weighted brain lesions, and 27% to 42% have clinically silent spinal cord lesions.

On T2-weighted imaging, brain lesions are typically 3 to 15 mm in diameter, round or ovoid, and have specific location patterns that are important for distinguishing them from other T2 hyperintense lesions, such as those representing small vessel ischemic change (Figs. 71.3 and 71.4; see Table 71.3). Active lesions tend to demonstrate postcontrast enhancement on T1-weighted images. Larger lesions in the cerebral hemispheres associated with mass effect, edema, or ring enhancement can resemble tumors and are known as *tumefactive lesions* (Fig. 71.5). Cortical lesions are sometimes not well visualized by standard MRI techniques but can certainly be present.

In patients with relapsing MS, gadolinium enhancement, which represents active inflammation and disruption of the blood–brain barrier, is the earliest phase of lesion development seen on conventional MRI (Fig. 71.6). Almost all new brain T2 lesions demonstrate enhancement on postgadolinium T1-weighted imaging, and 65% to 80% are hypointense on the corresponding pregadolinium T1-weighted sequence. Gadolinium enhancement typically resolves after 2 to 4 weeks. Persistent enhancement raises the possibility of an alternative diagnosis because only 3% to 5% of MS lesions enhance for more than 8 weeks. T2 lesions may become smaller, but they rarely disappear, whereas the majority of T1-hypointense lesions become isointense in 6 to 12 months, presumably as a result of resolution of edema and remyelination.

Spinal cord lesions are more common in the cervical than thoracic spine, appear hyperintense on T2-weighted imaging, and have a predilection for the white matter in the lateral and posterior columns. Adjacent gray matter is commonly involved. Lesions typically occupy less than half of the cross-sectional area of the cord and extend fewer than two vertebral segments (Fig. 71.7). Hypointense lesions on T1-weighted spinal cord MRI are uncommon in MS patients. Unlike gadolinium-enhancing brain lesions, active spinal cord lesions are frequently accompanied by clinical symptoms. However, asymptomatic spinal cord lesions are also common. Clinically silent spinal cord lesions are particularly useful for diagnosing MS in patients with vague neurologic symptoms and nonspecific findings on brain MRI because intramedullary cord lesions are rare in healthy people.

In general, RRMS patients have more gadolinium-enhancing lesions than those with progressive disease. Patients with SPMS tend to have more chronic black holes than those with the relapsing-remitting or primary progressive disease (Fig. 71.8). PPMS patients are more likely to have few T2 brain lesions and diffuse spinal cord abnormalities. However, MRI characteristics are not diagnostic of the subtypes of MS—these remain clinically based.

Conventional MRI lacks pathologic specificity, and areas of edema, demyelination, axonal damage, gliosis, and remyelination all appear as T2 hyperintensities. Furthermore, there is poor correlation between disability and T2-weighted abnormalities. Novel imaging techniques are emerging but remain in the research

FIGURE 71.3 Brain magnetic resonance imaging from relapsing-remitting multiple sclerosis (MS) patients. Axial **(A,B)** and sagittal **(C)** fluid-attenuated inversion recovery images demonstrate multiple periventricular white matter lesions. Many of the lesions are oriented perpendicular to the lateral ventricles and are the magnetic resonance imaging correlate of "Dawson fingers," which was originally a pathologic description of MS plaques. Also note the juxtacortical lesion in the right parietal lobe **(A)**. The location and morphology of the lesions is characteristic of MS.

realm for MS. These include quantitative susceptibility mapping, which can show iron deposition in the activated microglia of chronically activated lesions, even after the resolution of contrast enhancement. Central vein imaging is also being studied to help potentially distinguish demyelinating white matter lesions from nondemyelinating white matter lesions of unclear etiology.

Biomarkers

Examination of the CSF is a necessary aid for diagnosing MS and excluding alternative diagnoses. CSF typically contains fewer than six white blood cells (WBCs) per cubic millimeter and has a normal protein content in most patients with a CIS or established MS. A mild lymphocytic pleocytosis or elevated protein level is seen in about 35%. More than 50 WBCs per cubic millimeter or a protein content over 100 mg/dL are rarely observed and raise the possibility of an alternative diagnosis.

CSF immunoglobulin abnormalities are common. The immunoglobulin G (IgG) index, which measures intrathecal production of IgG, is elevated in 70% to 85% of MS patients. Isoelectric focusing followed by immunoblotting detects oligoclonal bands in more than 95% of patients (two or more bands detected in the CSF that are not present in the serum are considered abnormal). Treatment with corticosteroids lowers the IgG index but has no effect on oligoclonal bands. An elevated IgG index and the presence of oligoclonal bands are not specific to MS and are observed in 20% to 40% of patients with other inflammatory, demyelinating, or infectious diseases and occasionally other neurologic disorders, including the Guillain-Barré syndrome and other peripheral neuropathies. They can be seen transiently in the setting of CNS ischemia and CNS infections. Moreover, oligoclonal bands have been reported in up to 5% of healthy controls. Therefore, CSF abnormalities should always be considered in conjunction with clinical and MRI findings.

A single immunoglobulin band restricted to the CSF is of unclear significance and may be found in healthy individuals, as well as in a variety of illnesses, including CIS, MS, infectious and inflammatory diseases, CNS lymphoma, peripheral neuropathy, or migraine headaches. However, when the CSF is reexamined

FIGURE 71.4 Brain magnetic resonance imaging of the posterior fossa in a multiple sclerosis patient. A: An axial T2-weighted image reveals multiple infratentorial lesions consistent with multiple sclerosis. B: The lesions are not well visualized on the fluid-attenuated inversion recovery image. Although fluid-attenuated inversion recovery is a more sensitive sequence than T2 for demonstrating supratentorial lesions, it is suboptimal for detecting infratentorial lesions.

FIGURE 71.5 Brain magnetic resonance imaging from a patient with relapsing-remitting multiple sclerosis. Axial fluid-attenuated inversion recovery **(A)** and postgadolinium T1-weighted **(B)** images reveal a large ring-enhancing mass-like lesion with surrounding vasogenic edema in the left hemisphere. There is also a much smaller nonenhancing lesion in the right hemisphere. The findings are consistent with tumefactive multiple sclerosis.

FIGURE 71.6 Brain magnetic resonance imaging from a relapsing-remitting multiple sclerosis patient. A postcontrast T1-weighted image reveals multiple gadolinium-enhancing lesions. Gadolinium enhancement, which represents disruption of the blood-brain barrier and active inflammation, is the earliest phase of lesion development that can be detected on conventional magnetic resonance imaging.

after an average of 6 months, one-third of patients, the majority of whom have demyelinating disease, show a change from a monoclonal to oligoclonal pattern.

A high CSF level of myelin basic protein indicates damage to myelin and is not useful in differentiating MS from other illnesses, including cerebrovascular disease, infections, neoplasms, or inflammatory diseases. It is not recommended as a standard CSF test when evaluating for MS.

VEPs are sensitive for detecting clinically silent lesions in the anterior visual pathways, although they are no longer included in the MS diagnostic criteria. VEPs are abnormal (prolonged P100 latency or >6 ms interocular difference if the latencies are normal) in approximately 30% of patients with CIS other than optic neuritis and more than 50% of MS patients without a history of visual symptoms or clinical evidence of optic nerve dysfunction. However, abnormal VEPs may be observed in patients with other disorders, including compressive lesions of the optic nerve or chiasm, glaucoma, retinal disease, vitamin B_{12} deficiency, infectious diseases (eg, neuroborreliosis, neurosyphilis), systemic lupus erythematosus, and neurosarcoidosis.

MRI has largely supplanted the use of somatosensory and brainstem auditory-evoked potentials, which are rarely useful for identifying patients at increased risk for developing MS and are not included in the MS diagnostic criteria.

Optical coherence tomography (OCT) is a noninvasive technique that uses low-frequency infrared light to measure retinal nerve fiber layer (RNFL) thickness and macular volume. It has been used by ophthalmologists since 1990 to monitor glaucoma, and is now used in MS. Thinning of the RNFL occurs after optic neuritis as a result of loss of retinal axons. The eyes of MS patients without a history of optic neuritis also undergo thinning of the RNFL. OCT is used as a secondary and tertiary outcome measure in clinical trials and by some neurologists and ophthalmologists to follow patients with or without a history of optic neuritis.

Differential Diagnosis

In the absence of a definite diagnostic test, MS remains a diagnosis of exclusion, although revisions to the McDonald criteria have allowed for increased sensitivity and specificity of diagnosis. Most of the disorders that may mimic MS can be excluded by a detailed history, thorough examination, and appropriate laboratory tests and diagnostic studies.

Infections that may mimic MS include neuroborreliosis, neurosyphilis, and rarely progressive multifocal leukoencephalopathy (PML). Human T-lymphotropic virus type-1 and human

FIGURE 71.7 Cervical spine magnetic resonance imaging from a relapsing-remitting multiple sclerosis patient. Axial **(A)** and sagittal **(B)** T2-weighted images reveal intramedullary lesions at C5-C6 consistent with demyelination. Also note the lesion at the cervicomedullary junction.

FIGURE 71.8 Brain magnetic resonance imaging from a patient with secondary progressive multiple sclerosis. A sagittal fluid-attenuated inversion recovery image reveals multiple periventricular white matter lesions consistent with multiple sclerosis. Note that many of the lesions are hypointense on the pregadolinium T1-weighted image.

immunodeficiency virus should be considered in patients with a progressive myelopathy.

Acute disseminated encephalomyelitis (ADEM) may be impossible to distinguish from a first attack of MS. However, it is more likely to follow an infection or vaccination and is significantly more common in children. Patients with ADEM are typically encephalopathic, which is rare in MS. Although patients with sarcoidosis may initially present with neurologic symptoms, evaluation usually reveals evidence of systemic sarcoidosis.

Other systemic autoimmune diseases and vasculitides that should be considered in the differential of MS include Behçet syndrome, vasculitis, Sjögren syndrome, lupus, antiphospholipid antibody syndrome, and Susac syndrome. Behçet disease is a form of vasculitis that can involve blood vessels of all sizes within both the arterial and venous circulation. It is commonly associated with genital/oral ulcers and may also cause cutaneous, ocular, and neurologic disease. Behçet disease is more common along the ancient Silk Road, from East Asia to the Mediterranean, and it is most common in Turkey. Other vasculitides may mimic MS as well. Granulomatosis with polyangiitis (Wegener) causes necrotizing inflammation involving small- to medium-sized vessels along with the upper and lower respiratory tract. Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) causes an eosinophilic, necrotizing vasculitis that also affects small- to medium-sized vessels and the respiratory tract. Both granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis are associated with antinuclear cell antibodies and are referred to as antinuclear cell antibodies–associated vasculitides. They may have neurologic manifestations, which can include peripheral and cranial neuropathies along with CNS mass lesions, external ophthalmoplegia, and sensorineural hearing loss. Sjögren syndrome is a systemic autoimmune disease characterized by dry eyes/mouth along with a wide variety of other clinical symptoms. It can be associated with neurologic symptoms including peripheral neuropathies and focal lesions involving the brain, optic nerves, and/or spinal cord. Systemic lupus erythematosus may have neurologic manifestations including headache, stroke, neuropsychiatric symptoms, optic neuritis, transverse myelitis, and white matter lesions on brain MRI. Antiphospholipid syndromes may be associated with lupus or occur as a primary condition. Antiphospholipid syndromes are characterized by arterial, venous, and/or small vessel thromboembolic events and are associated with the persistent presence of antiphospholipid antibodies. It has been associated with white matter lesions on brain MRIs, which can mimic MS lesions. Susac syndrome is an autoimmune microangiopathic endotheliopathy that affects brain, retina, and cochlea and results in encephalopathy, hearing loss, and branch retinal artery occlusions. It may be mistaken for MS because of prominent white matter lesions that are observed on brain MRI.

Demyelinating episodes have also been associated with certain medications. Drug-induced demyelination has been associated with anti-tumor necrosis factor monoclonal antibodies and should be considered in patients with Crohn disease or rheumatoid or psoriatic arthritis. Anti-PD-1, PD-L1, and CTLA4 molecules are checkpoint inhibitors used for many types of malignancy. Neurologic complications, including apparent demyelination, have been described with these medications as well.

NMOSD may be difficult to distinguish from MS, particularly early in the disease, in patients with recurrent optic neuritis and minimally abnormal brain MRI or in patients with brain MRI findings more characteristic of MS. AQP4-IgG seropositivity may help differentiate the diseases. MOG spectrum disease can also be difficult to distinguish from MS, and it can overlap with a number of conditions, such as ADEM, optic neuritis, NMOSD, and even MS. These disorders are covered in detail later in this chapter.

Neoplasms (especially primary CNS lymphoma and gliomas) occasionally enter the differential diagnosis. Hyperacute onset of symptoms suggests stroke. Primary lateral sclerosis may simulate PPMS but does not relapse and is monosymptomatic. The MRI and CSF analysis usually help differentiate the two diseases. Hereditary spastic paraparesis should be considered in patients with a progressive spastic paraparesis, especially if there is a family history of similar illness. Other causes of a progressive myelopathy that should be considered in patients suspected of having progressive MS include adrenomyeloneuropathy, vitamin B_{12} deficiency, copper deficiency, spondylotic myelopathy, spinal cord tumors, and a spinal dural arteriovenous fistula.

Management

Three different categories of medications are used for MS: medications for acute exacerbations, disease-modifying medications, and symptomatic medications. Optimal disease management often requires a multidisciplinary approach implementing pharmacologic and nonpharmacologic strategies.

Treatment of Acute Exacerbations

High-dose intravenous (IV) corticosteroids hasten recovery from acute exacerbations but do not seem to affect the degree of recovery. A typical regimen consists of a 3- to 5-day course of 1,000 mg of IV methylprednisolone, typically without an oral prednisone taper, because there is no significant adrenal gland suppression with a short period of IV steroids, and lower dose oral steroids were not effective in treating demyelinating events. Some patients with severe attacks seem to respond better to an

additional 2 to 5 days of treatment. Because treatment does not seem to affect long-term outcome, not every MS exacerbation (eg, mild sensory symptoms) requires corticosteroid treatment. In the Optic Neuritis Treatment Trial, patients who received oral prednisone 1 mg/kg/d did not improve any more quickly than the placebo-treated group. Furthermore, treatment with oral prednisone was associated with an increased risk of subsequent optic neuritis. Therefore, there does not appear to be a role for low-dose oral corticosteroids in the treatment of MS acute exacerbations LEVEL 1.[1] High-dose oral steroids, however, have been shown to be equivalent to IV dosing and can be substituted for IV steroids.

Fever and infections, including otherwise asymptomatic urinary tract infections, can cause transient worsening or recurrence of MS symptoms without evidence for new brain inflammation indicative of new disease activity. This is known as a *pseudoexacerbation*. Infections should be excluded in the setting of new or worsening symptoms before treatment with corticosteroids is initiated and fevers should be treated aggressively.

Plasma exchange may be warranted for the treatment of acute relapses that result in significant disability despite high-dose IV corticosteroid therapy. In a small but well-designed study, 42% of patients with severe demyelinating events that did not respond to high-dose IV corticosteroids had marked functional improvement after seven plasma exchanges, which took place an average of more than 40 days after the onset of symptoms. The investigators of a larger retrospective study reported similar results and concluded that plasma exchange may be effective, even when initiated more than 60 days after the onset of an acute demyelinating event.

Disease-Modifying Drugs

Disease-modifying therapies are the mainstay of treatment for MS. These medications are most effective for relapsing MS, where they have been shown to reduce the frequency of relapses and the accumulation of disease on MRI. Most also appear to slow confirmed disability progression over time. Emerging evidence strongly supports that disease-modifying therapies are most effective when initiated early in the course of disease, at the time of first clinical presentation, and that treating patients with highly effective therapies at the time of disease onset results in better outcomes. There has therefore been a paradigm shift in treatment philosophies for MS, and most experts now recommend early treatment with highly effective medications.

Disease-modifying medications are far less effective in patients with a progressive disease phenotype. When progressive MS patients continue to exhibit disease activity (eg, new lesions on MRI or clinical relapses superimposed on a progressive course), there may be a continued role for disease-modifying medications. Among the currently approved therapies, siponimod was recently approved for use in active SPMS, and ocrelizumab is approved for use in PPMS LEVEL 1.[2,3]

The treatment landscape for MS has changed considerably over the last decade. The U.S. Food and Drug Administration (FDA) approved the first oral therapy, fingolimod in 2010. This was followed by the approval of teriflunomide (2012), dimethyl fumarate (2013), alemtuzumab (2014), ocrelizumab (2016), siponimod (2019) and cladribine (2019). Table 71.6 summarizes available therapies for relapsing forms of MS. Treatment decisions should be based on efficacy in relationship to potential side effects and concomitant medical issues. The lack of rationale for "escalation therapy" has been recently addressed because patients with more severe disease who were treated with natalizumab or alemtuzumab at disease onset had less accumulation of disability over 5 years than patients with more mild disease who were treated with less effective therapies. This is consistent with clinical trials in MS indicating that outcomes are significantly better with earlier as compared to delayed therapy. Thus, for most patients, highly effective treatments should be initiated at the time of diagnosis.

Ocrelizumab and Rituximab

Ocrelizumab is a monoclonal antibody against CD20, a surface marker for mature B cells. It depletes B cells while sparing stem cells and plasma cells and is highly effective for reducing relapses and new brain lesions in relapsing MS LEVEL 1.[4] In phase 3 clinical trials, RRMS patients receiving ocrelizumab developed 94% fewer gadolinium-enhancing lesions than patients treated with high-dose interferon β-1a. Ocrelizumab was also modestly effective for reducing disability progression in PPMS patients, making it the first disease-modifying therapy to affect PPMS LEVEL 1.[2] Ocrelizumab is a humanized version of the chimeric anti-CD20 antibody, rituximab, which has a similar mechanism of action. Rituximab is not FDA approved for MS but has been used off-label for over a decade to treat relapsing disease. Both ocrelizumab and rituximab may increase risks of infection, particularly with long-term use, and infusion reactions are fairly common during drug administration.

Alemtuzumab

Alemtuzumab is a monoclonal antibody directed against CD52. It transiently depletes both T and B cells effectively "rebooting" the immune system. Alemtuzumab is highly effective for treating relapsing MS, reducing relapses, MRI evidence of disease, and disability progression LEVEL 1.[5,6] It is given in two courses of therapy, separated by 12 months. Beyond that time, patients require further immunotherapy only if they develop new evidence of disease activity. Among patients enrolled in the phase 3 trials of alemtuzumab, approximately 60% required no retreatment for 3 years after their last alemtuzumab infusion.

Although highly effective for preventing MS disease activity, alemtuzumab has substantial side effects as approximately one-third of treated patients develop secondary autoimmunity in the form of thyroiditis or kidney disease, and a small number of patients had strokes/intracerebral hemorrhages/arterial dissections in conjunction with their infusions. Extensive monitoring is needed during infusions and for 5 years after the last infusion.

Natalizumab

Natalizumab is a humanized monoclonal antibody against the α4-subunit of α4β1 integrin expressed on the surface of activated T cells. It blocks the binding between α4β1 integrin and its receptor, vascular cell receptor molecule-1 on the vascular endothelial surface. Because this interaction is essential for lymphocyte migration, the drug prevents activated T cells from accessing the CNS. Natalizumab is highly effective for reducing relapses and MRI evidence of disease activity in relapsing MS LEVEL 1.[7,8] However, because it is associated with PML, a sometimes fatal brain infection, it is used in conjunction with antibody testing for John Cunningham virus to predict risk of PML. Six percent of patients develop persistent anti-natalizumab antibodies, which are associated with a clear loss of efficacy and an increased risk of infusion-related hypersensitivity reactions.

TABLE 71.6 Overview of Disease-Modifying Therapies for Relapsing Forms of Multiple Sclerosis Listed by Relative Efficacy

Treatment	Dosage	Potential Side Effects	Monitoring	Monitoring Frequency	Efficacy
Ocrelizumab	2 doses of 300 mg IV q2wk for initiation 600 mg IV q6mo for maintenance	Slight increase in risk of infection Infusion reactions	CBC, CMP QuantiFERON or TB skin test Quantitative immunoglobulins Chronic hepatitis panel Lymphocyte subsets	Baseline	High
			CBC, CMP	q6mo	
			Hepatitis panel Quantitative immunoglobulins	Periodically	
Rituximab (off-label use)	1,000 mg × 2 doses, 2 wk apart (initiation) 500-2,000 mg q6mo Dosing varies.	Slight increase in risk of infection Infusion reactions	As for ocrelizumab Lymphocyte subsets may be monitored and subsequent dosing based on whether circulating B cells are detectable.	As for ocrelizumab	High
Alemtuzumab	5 doses of 12 mg IV daily for initiation 3 doses of 12 mg IV daily after 12 mo Further treatment only as needed	Increased risk of infection Infusion reactions Secondary autoimmunity (thyroid, kidney) Risk of stroke/intracerebral hemorrhage/arterial dissection with infusions	UA, TFT, CBC, CMP, VZV titer, QuantiFERON or TB skin test, lymphocyte subsets Skin check GYN/Pap recommended	Baseline	High
			UA, BMP, CD4 counts (until normal), TFT	Monthly until 48 months after last infusion	
			LFTs, lymphocyte subsets Skin check GYN/Pap recommended	Annually	
Natalizumab	300 mg IV q4wk	Progressive multifocal leukoencephalopathy LFT abnormalities Hypersensitivity reaction	JCV Ab LFTs MRI brain	JCV⁻ patients: Check labs q6mo and MRI annually.	High
				JCV⁺ patients: Check JCV q3mo and MRI q6mo.	
Cladribine	Year 1: 1.75 mg/kg First course: administered over 4-5 d Second course: administered over 4-5 d; 23-27 d after first course	Malignancy Teratogenicity Infections Lymphopenia LFT abnormalities	CBC, LFTs Pregnancy test HIV Hepatitis screen (B and C) Varicella immunity	Before each treatment course	Moderate to high

TABLE 71.6 Overview of Disease-Modifying Therapies for Relapsing Forms of Multiple Sclerosis, Listed by Relative Efficacy *(continued)*

Treatment	Dosage	Potential Side Effects	Monitoring	Monitoring Frequency	Efficacy
Siponimod	Titration Maintenance dose is 1-2 mg daily depending on CYP2C9 genotype	As for fingolimod	As for fingolimod EXCEPT first-dose observation done only if cardiac history CYP2C9 genotype	Prior to first dose	Moderate
			Macula exam Spirometry	If visual or respiratory symptoms	
			CBC, LFTs	q6mo	
Dimethyl fumarate	240 mg orally twice a day	Gastrointestinal upset Flushing LFT abnormalities Lymphopenia	CBC, LFTs	Baseline and q6mo	Moderate
Teriflunomide	7 mg or 14 mg orally daily	Gastrointestinal side effects Hair thinning LFT abnormalities (black box warning: hepatic failure) Hypertension Tuberculosis reactivation	QuantiFERON gold or TB skin test CBC, LFTs	Baseline	Low to moderate
			LFTs	Monthly for first 6 months after initiation	
			CBC, LFTs	q6mo	
IFNβ-1b IFNβ-1a IFNβ-1a pegylated IFNβ-1a	250 μg SC every other day 30 μg IM every week 22 μg or 44 μg SC three times weekly 125 μg SC every other week	Flulike symptoms Injection site reactions LFT abnormalities Leukopenia Neutralizing antibodies Depression Injection site necrosis (rare)	CBC LFTs TFTs	q6-12mo	Low to moderate
Glatiramer acetate	20 mg SC daily or 40 mg SC three times weekly	Site reactions Lipoatrophy Immediate postinjection reactions	None	NA	Low to moderate

Abbreviations: BMP, basic metabolic panel; CBC, complete blood count; CMP, complete metabolic panel; CYP2C9, Cytochrome P450 Family 2 Subfamily C Member 9; ECG, electrocardiogram; GYN/Pap, gynecologic exam with Pap smear; HIV, human immunodeficiency virus; IFNβ, interferon β; IM, intramuscular; IV, intravenous; JCV, John Cunningham virus; LFT, liver function test; MRI, magnetic resonance imaging; PML, progressive multifocal leukoencephalopathy; SC, subcutaneous; TB, tuberculosis; TFT, thyroid function test; UA, urinalysis; VZV, varicella-zoster virus.

Cladribine

Cladribine is an oral medication for MS that reduces relapses, MRI activity, and disease progression in relapsing forms of MS LEVEL 2.[9] Its effects are thought to be mediated by cytotoxic effects on B and T lymphocytes through impairment of DNA synthesis. Cladribine is moderately to highly effective and is administered in two treatment cycles over the course of 2 years. After completing a 2-year course of cladribine, no further immunotherapy is recommended unless new disease activity develops. Cladribine may increase risk of malignancy, so patients should remain up-to-date on all recommended malignancy screenings.

Fingolimod

Fingolimod is a functional antagonist of the sphingosine-1-phosphate receptors 1, 2, 3 and 5. It prevents egress of lymphocytes from peripheral lymph nodes. Reduction in relapse rate and MRI outcomes was significant compared to placebo and to weekly intramuscular interferon β-1a in two large randomized, double-blind, placebo-controlled trials LEVEL 1.[10,11] Fingolimod has rarely been associated with serious infections, including cryptococcal infections, disseminated herpes, and PML.

Siponimod

Siponimod is a second-generation sphingosine-1-phosphate modulator, differing from fingolimod in that it affects primarily sphingosine-1-phosphate receptors 1 and 5. It reduced relapse frequency and MRI activity and slowed disease progression for patients with active SPMS LEVEL 1[3] and is approved for patients with relapsing and active progressive disease. Side effects are similar to those of fingolimod, although due to its recent approval, less follow-up data is available.

Dimethyl Fumarate

Dimethyl fumarate is a fumaric acid ester shown to be effective in reducing relapse frequency and MRI activity in relapsing forms of MS LEVEL 3.[12,13] Its mechanism of action is hypothesized to be related to scavenging free radicals and acting through modulation of NF-kB and Nrf2 pathways. It also has direct effects on lymphocytes, reducing the frequency of memory B and T cells and expanding the circulating naïve lymphocyte population. The drug also downregulates aerobic glycolysis in vitro. A minority of patients treated with dimethyl fumarate develop profound lymphopenia, and PML has rarely been reported among treated patients.

Teriflunomide

Teriflunomide is a pyrimidine synthesis inhibitor, which slows expansion of activated effector lymphocytes. Modest efficacy in relapse rate reduction as well as reduction in sustained disability progression was shown in large double-blind, placebo-controlled trials LEVEL 1.[14,15]

β-Interferons and Glatiramer Acetate

The β-interferons and glatiramer acetate were early therapies used to treat RRMS, but in the present era of more effective therapies, they are of limited use save for glatiramer acetate, which appears to be relatively safe during pregnancy. Although they reduce relapses and improve outcomes compared to placebo, they are significantly less effective than more recently approved immunotherapies LEVEL 1.[4,16-19] Interferons have multiple mechanism of action. Their therapeutic effects may be due to antiproliferative action, downregulation of costimulatory molecules, decrease of proinflammatory cytokines, or through effects on matrix metalloproteinases and adhesion molecules, which limit trafficking of T lymphocytes into the CNS. The beneficial effects of glatiramer acetate, a synthetic polypeptide composed of the four amino acids L-alanine, L-glutamic acid, L-lysine, and L-tyrosine, may result from reactive Th2 cells that cross the blood-brain barrier and increase the secretion of suppressor-type cytokines and downregulate inflammatory activity within the CNS, a process known as *bystander suppression*.

Neutralizing antibodies (NAbs) develop in 15% to 25% of patients treated with high-dose interferons, typically developing between 6 and 18 months after the initiation of treatment and only rarely after more than 2 years of therapy. Although they may be transient, persistent high-titer NAbs (>100 NU/mL) are associated with a reduced therapeutic effect. Individuals developing evidence of NAbs should discontinue interferon treatment permanently and initiate a different disease-modifying therapy.

Mitoxantrone

Mitoxantrone is an anthracenedione with immunosuppressive and immunomodulatory properties. It is FDA approved for SPMS as well as highly active relapsing MS. However, due to a substantial risk for cardiac toxicity, it is no longer used in clinical practices.

Symptom Management

Therapies to alleviate the daily symptoms of MS are integral part of patient care. Successful treatment often involves a combination of pharmacotherapy with nonpharmacologic measures, such as rehabilitation, exercise, or lifestyle and environmental modifications. See **Table 71.7** for an overview of symptomatic management of common MS symptoms.

Spasticity

Management of spasticity includes evaluation and treatment of potentially exacerbating factors. Once exacerbating factors are minimized, a combination of physical therapy interventions and pharmacologic management is optimal. The most commonly used agents are baclofen and tizanidine alone or in combination. Common adverse effects of baclofen include limb weakness, sedation, and confusion. At higher doses, weakness may negate the benefit of spasticity reduction. Abrupt discontinuation of baclofen can result in seizures, confusion, hallucinations, and a marked increase in muscle tone. Some of the systemic side effects of baclofen can be mitigated by intrathecal administration in selected patients with substantial lower extremity spasticity. The use of tizanidine is mainly limited by drowsiness. The use of benzodiazepines has largely been supplanted by baclofen and tizanidine, which are better tolerated. Botulinum toxin is effective for focal spasticity and has been approved for this purpose.

Gait Disturbance

Occupational and physical therapy are the mainstays of treatment for motor impairment. For optimal effectiveness, therapists should be familiar with MS and take the diagnosis into account when formulating a rehab plan. The potassium channel blocker dalfampridine, which is a sustained release formulation of 4-aminopyridine, enhances conduction across demyelinated nerve fibers. It improved leg strength and walking speed in some patients with relapsing and progressive forms of MS in two therapeutic trials LEVEL 1.[20] Dalfampridine increases the risk of seizures, especially at higher doses, and is contraindicated in those with history of seizures or impaired kidney function. The risk of seizure appears to be low with the approved dose of dalfampridine, which is 10 mg twice daily.

Mood Disturbance

Depression responds well to psychotherapy and antidepressants, alone or in combination. Amitriptyline is effective for pseudobulbar affect (pathologic laughing or crying), as is a mixture of dextromethorphan and quinidine LEVEL 1.[21]

Cognitive Impairment

Cognitive impairment may develop early in MS, and formal neuropsychological testing is warranted at the time of diagnosis to establish a baseline. An MS-related cognitive decline is frequently confounded by mood disorders, sleep disturbances, and fatigue. Thus, although there are no clearly effective treatments for MS-related cognitive impairment, eliminating confounding factors may lead to improvements for some patients. Patients may benefit from cognitive remediation and strategies to compensate for deficits. Physical exercise may also improve cognitive symptoms. Medications, including donepezil and memantine, have not been helpful for MS-induced cognitive dysfunction, and polypharmacy can worsen cognitive function. Disease-modifying drugs that minimize lesion development, tissue destruction, or brain atrophy may limit cognitive decline.

Bladder/Bowel Dysfunction

Bladder dysfunction in MS can be well characterized by a urologic evaluation and urodynamic studies. A combination of anticholinergic therapy and an α-adrenergic antagonist (doxazosin, prazosin, tamsulosin, terazosin) may facilitate emptying in individual with sphincter detrusor dyssynergia. Catheterization (preferably clean intermittent catheterization) is the mainstay of therapy in patients with detrusor hypocontractility and emptying difficulties. Those unable to tolerate medications or perform self-catheterization may require an indwelling catheter. Urologic follow-up is necessary for patients with a chronic indwelling catheter to monitor for the development of urinary tract and genital complications.

Tremor

Numerous medications have been evaluated for treating MS tremor, including carbamazepine, clonazepam, gabapentin, levetiracetam, primidone, ondansetron, propranolol, and tetrahydrocannabinol. However, these agents are rarely effective, and

TABLE 71.7 Management of Multiple Sclerosis Symptoms

Symptom	Nonpharmacologic Approaches	Pharmacologic Approaches (Starting Dosage)
Spasticity	Physical and occupational therapy Exercise Evaluation of aggravating factors which may include the following: • Urinary tract infection • Decubitus ulcers • Pain • Constipation • Tight-fitting garments	Baclofen (oral 10 mg three times a day or intrathecal) Tizanidine (4 mg every bedtime) Benzodiazepines (varies) Botulinum toxin Gabapentin (300 mg three times a day)
Weakness	Physical and occupational therapy	Dalfampridine (10 mg twice a day)
Depression	Psychotherapy Support groups	Selective serotonin reuptake inhibitors Serotonin norepinephrine reuptake inhibitors
Pseudobulbar affect	Psychotherapy to manage triggers	Dextromethorphan/quinidine (20/10 mg twice a day) Amitriptyline (10 mg every bedtime)
Fatigue	Improve sleep habits • Cognitive behavioral therapy • Sleep hygiene Energy conservation techniques Evaluation of other causes of fatigue including the following: • Anemia • Thyroid dysfunction • Sleep apnea • Elevated core body temperature • Side effects of other medications	Amantadine (150 mg twice a day) Modafinil (100 mg once a day) Armodafinil (150 mg once a day) Methylphenidate (10 mg once a day)
Sexual dysfunction	Psychotherapy and relationship counseling to help couples manage sexual difficulties Mechanical vibrators and vacuum devices to enhance blood flow, increase lubrication, and stimulate orgasm	Selective phosphodiesterase 5 inhibitors for erectile dysfunction Estrogen creams for vaginal dryness
Cognitive impairment	Neuropsychological testing to define areas of deficit, identify areas of relative strength for compensatory strategies Cognitive remediation	No clearly effective pharmacotherapy
Urinary dysfunction	Urodynamic studies to define specific type of dysfunction—failure to store or empty Biofeedback Evaluate for infection. Intermittent catheterization	Anticholinergics Mirabegron (25 mg once a day) α-Adrenergic antagonist Botulinum toxin Desmopressin for nocturia (0.1 mg every bedtime)
Bowel dysfunction	Biofeedback Dietary changes to increase fiber Increase water intake for constipation. Scheduled defecation	Stool softener Stimulant laxative Osmotic laxative
Tremor	Deep brain stimulation	Primidone (25 mg every bedtime) Propranolol (20 mg twice a day) Clonazepam (0.5 mg twice a day) Ondansetron (8 mg twice a day)
Paroxysmal symptoms (trigeminal neuralgia, paroxysmal dystonia)	Avoidance of triggers	Carbamazepine (100 mg twice a day) Acetazolamide (250 mg twice a day) Phenytoin (100 mg three times a day) Lamotrigine (100 mg once a day) Baclofen (10 mg three times a day)
Pain	Avoidance of triggers Exercise/physical therapy	Gabapentin (300 mg three times a day) Pregabalin (75 mg twice a day) Amitriptyline (25 mg every bedtime) Duloxetine (30 mg daily) Venlafaxine (37.5 mg twice a day)

tremor can be the most difficult MS symptom to treat. Thalamic deep brain stimulation may result in dramatic improvement. Stable MS patients with disabling tremor for at least 1 year despite medical therapy who have no significant cognitive dysfunction, speech or swallowing problems, or other deficits in the affected limbs may be good candidates.

Pain

If treatment is warranted, dysesthesias and pain usually respond to anticonvulsants and antidepressants, either used alone or in combination. Gabapentin, pregabalin, amitriptyline, nortriptyline, and duloxetine commonly provide relief. Myelopathic pain responds to opioids, which may be necessary in some patients.

Referral to a pain specialist may be helpful for patients with refractory pain.

Pregnancy and Breastfeeding

Pregnancy is mildly protective in MS, particularly during the third trimester when there is a 70% reduction in the annualized relapse rate compared with the year prior to pregnancy. However, when MS is left untreated, about 30% of women have a relapse in the first 3 months postpartum before the risk returns to the prepregnancy rate at 4 to 6 months after delivery. These effects may be the result of changes in Th1 and Th2 immune responses mediated by estriol or vitamin D, both of which are markedly elevated during the final trimester of pregnancy and fall abruptly after delivery; other hormonal changes that occur during pregnancy may also play a role.

Women with relapses during pregnancy or in the year prior to pregnancy are more likely to have a relapse in the first 3 months postpartum than women without relapses during these periods, but it is impossible to accurately predict who will have a relapse. Steroids may be used during pregnancy if necessary to treat relapses.

Most women desiring pregnancy discontinue MS disease-modifying therapy prior to conception and remain off treatment during pregnancy. If therapy is continued during pregnancy, glatiramer acetate is most often used. There may be an emerging role for longer acting disease-modifying therapies in women who are planning future pregnancies, but this has not been formally studied and it is not recommended to give these medications during a known pregnancy.

Mothers with MS who wish to attempt breastfeeding may do so, although close monitoring is warranted. One study found that exclusive breastfeeding for the 2 months after delivery decreased the relapse risk, but other studies had conflicting results. Breastfeeding should not be considered a substitute for disease-modifying therapy. Clinical and radiologic reassessment should be performed postpartum, and decisions about ongoing breastfeeding should be made based on those assessments. Limited data are available related to the safety of disease-modifying therapies while breastfeeding. Glatiramer acetate appears to be safe. Large monoclonal antibodies (eg, natalizumab and ocrelizumab) are unlikely to be secreted into breast milk in large quantities and would most likely be destroyed in the infant's gastrointestinal tract. Direct data on their use during lactation is lacking. No evidence is available regarding the safety of oral MS medications during lactation, and most neurologists recommend avoiding them during breastfeeding.

Vaccination

Infections, including minor upper respiratory infections, increase the risk of MS exacerbations. Strategies that minimize the risk of infection should be incorporated. A prospective, randomized, double-blind, placebo-controlled trial showed that influenza immunization did not increase the risk of relapse or disease progression LEVEL 1.[22] Hepatitis B, tetanus, and varicella vaccines also appear to be safe in MS patients. Because there is no evidence that vaccines trigger MS exacerbations, most MS patients should be encouraged to receive all routine immunizations. In a patient who is undergoing an MS relapse, it is probably best to delay immunizations for 4 to 6 weeks because the goal of relapse management is to diminish the immune system's reactivity, and vaccination has the opposite effect.

Several of the immunosuppressive medication therapies used to treat MS may increase the risk of certain vaccines. Live vaccines should not be administered to patients currently treated with ocrelizumab, rituximab, alemtuzumab, mitoxantrone, fingolimod, and siponimod. Any necessary live vaccines should be administered at least 4 weeks before initiating treatment with these medications. Patients receiving these and other immunomodulatory medications for MS can safely receive nonlive vaccines, however. The resultant immune response to vaccination is frequently less robust than for individuals not on immunomodulatory medications but is typically sufficient for immunity.

Pediatric Multiple Sclerosis

Between 3% and 10% of MS patients present before age 16, and less than 1% of cases present at ages younger than 10. Pediatric MS cases are highly likely to present with a relapsing variant of the disease (98% have RRMS), and the female predominance is even more striking in adolescent patients compared to adults, with a female:male ratio of about 4.5:1. In patients younger than age 11, however, the female:male ratio is closer to 1:1. Pediatric MS patients are more likely than adults to experience an aggressive disease onset with multifocal presentations and high relapse rates early in disease. Pediatric patients also present with encephalopathy (eg, ADEM) more frequently than adults.

Although they frequently recover well from early relapses, patients with pediatric MS experience a failure of age-expected brain growth. Cognitive impairment is consistently reported in about one-third of patients. Moreover, although the time to SPMS is longer in pediatric-onset MS compared to adult-onset MS, the young age of onset means that these patients are still developing substantial physical disability in early adulthood.

As with adult-onset disease, early treatment is key to minimizing disability in pediatric-onset MS. Existing evidence suggests that pediatric and adult MS patients share pathophysiology, but only a few immunomodulatory therapies have been formally tested in the pediatric populations, and the rarity of the diagnosis has made recruitment for trials challenging. Retrospective studies of interferon β and glatiramer acetate have been performed, and these drugs are considered safe and frequently used. Natalizumab, dimethyl fumarate, and fingolimod have undergone trials in pediatric populations. In the phase 3 fingolimod trial, fingolimod was superior to subcutaneous interferon β-1a LEVEL 2.[23] Trials of teriflunomide and alemtuzumab are ongoing. B-cell depleting agents are also frequently used off-label in the pediatric population.

Schilder disease, or myelinoclastic diffuse sclerosis, is a vanishingly rare pediatric form of demyelinating disease characterized by formation of bilateral plaques in the centrum semiovale with pathology consistent with MS without additional lesions in the CNS in the setting of normal peripheral nervous system function, normal adrenal function, and no deficit in very long-chain fatty acids. A handful of cases have been reported since the original description by Schilder in 1912. There is controversy regarding the potential contamination of case series with children eventually found to have adrenoleukodystrophy.

Outcomes

MS is an extremely variable illness, and much of the data on the natural history of MS precede the availability of highly effective treatments. In patients who have been treated early with highly effective treatment, one might suspect that the individual risk of disability is less than that of the untreated patient. However, there have not been recent long-term studies to determine prognosis or to update statistics on chance of progression from RRMS

to SPMS. Therefore, counseling patients with early MS poses a major challenge for clinicians.

Brain MRI abnormalities after an initial demyelinating event provide important prognostic information regarding the development of MS. Fifty-one percent of optic neuritis patients with at least three brain MRI T2 hyperintense lesions will meet diagnostic criteria for clinically definite MS within 5 years compared to 16% of those with optic neuritis and a normal brain MRI. Using older definitions of CIS (prior to the 2017 McDonald criteria, which incorporates oligoclonal bands into diagnosis), definite MS developed within 20 years for 82% of CIS patients with at least one brain MRI T2 lesion compared with 21% with a normal baseline brain MRI. In previous CIS trials, 41% to 50% of patients were diagnosed with definite MS within 2 to 3 years. The risk of developing MS was greatest in patients with more than eight T2 hyperintense lesions or at least one gadolinium-enhancing lesion on their baseline brain MRI.

In general, higher numbers of brain MRI lesions at the time of clinical presentation is associated with greater risk of long-term disability. There is also a modest correlation between changes in MRI T2 lesion volume over the first 5 years and long-term disability. However, possible outcomes are wide ranging. In one natural history study, 45% of those with at least 10 lesions on initial brain MRI had reached estimated disability status scale (EDSS) of 6 (a score indicative of needing a walking aid of any sort) after 20 years, but 35% had only mild disability. However, the EDSS does not measure cognitive impairment or neuropsychiatric disability well, and such changes were therefore likely missed in these historical studies.

Although the course of MS is essentially impossible to predict in an individual patient, female sex, younger age at onset, and little disability 5 years after onset are generally favorable prognostic signs. Male sex, older age at onset, frequent attacks early in the course of the disease, a short interval between the first two attacks, incomplete recovery from the first attack, rapidly accumulating disability, cerebellar involvement as a first symptom, and progressive disease from onset are associated with worse outcome. Optic neuritis as a first attack is associated with a favorable short- and intermediate-term outcome, but 20-year disability is similar among patients who present with optic neuritis, brainstem, or spinal cord syndromes.

In one natural history study, 24% of patients with a CIS under pre-2017 definitions, who were followed for an average of 4 years, reached an EDSS score of 6 or more (EDSS 6 is defined as unable to walk 100 m without unilateral assistance), and 40% of those followed for 6 to 15 years entered the secondary progressive phase of the disease. These findings indeed demonstrate that our prior concepts of "CIS" were in large part semantics because these patients ultimately had MS pathology.

Some patients have a very mild form of RRMS with minimal or no disability at least 10 years after disease onset, which is often referred to as *benign multiple sclerosis*. This term, however, should be used with caution and is truly a matter of controversy because there are many measures of disability that are not being measured adequately by scales such as the EDSS, with cognitive dysfunction being the most concerning example. Neuropsychological testing reveals cognitive impairment in approximately 20% to 45% of patients considered to have benign MS. Therefore, the diagnosis of benign MS should include an assessment of cognitive function and only be considered in retrospect and after prolonged follow-up.

The Marburg variant of MS is a rare, fulminant, and usually monophasic illness that typically results in death within 1 year. It can be difficult to differentiate from severe ADEM. Pathologically, it is characterized by robust macrophage infiltrate and destruction of axons as well as demyelination and prominent tissue necrosis.

NEUROMYELITIS OPTICA SPECTRUM DISORDER

Introduction

NMOSD is a severe inflammatory demyelinating disease of the CNS that is distinct from MS. Formerly called *Devic disease*, it was originally considered a subtype of MS characterized by the co-occurrence of acute or subacute optic neuritis and transverse myelitis. It is now recognized that NMOSD actually has a broader clinical phenotype. Although there is overlap with the presentation of MS, NMOSD has a distinct pathologic antibody and pathologic features of the optic neuritis and myelitis are distinct from those seen in MS.

Epidemiology

The true incidence and prevalence of NMOSD are unknown. However, the disease is much less common than MS with an estimated prevalence of approximately 5 per 100,000 individuals. NMOSD usually begins in the fourth decade, but the onset may occur during childhood or after age 70 years. The reported incidence is up to 10 times higher in women, and nonwhite individuals are more commonly affected than whites.

Pathobiology

AQP4-IgG is a sensitive and highly specific serum autoantibody that is present in serum for about 70% of NMOSD patients. The antibody may also be detected in CSF, but serologic testing has a higher sensitivity and is preferred. Pathogenicity of the AQP 4-IgG has been demonstrated by passive transfer in animal models. AQP4 is the main water channel in the CNS and is the target antigen for seropositive cases of NMOSD. AQP4 is located primarily in perivascular and subpial astrocytic foot processes. It is expressed at high levels within the optic nerves, hypothalamus, brainstem, periventricular regions, and gray matter of the spinal cord. AQP4 loss may impair water homeostasis and glutamate transport and lead to oligodendrocyte injury, demyelination, and axonal damage. The circumventricular organs around the third and fourth ventricles contain a high density of AQP4, and this may explain the clinical syndrome of intractable nausea, vomiting, and hiccups as well as hypothalamic dysfunction.

Acute NMOSD lesions are far more destructive than those seen in MS. The NMOSD lesions are characterized by extensive demyelination and axonal damage and contain an inflammatory infiltrate consisting mainly of macrophages, B lymphocytes, eosinophils, and granulocytes. T lymphocytes are sparse. The immunoglobulin and products of complement activation are deposited in a distinctive perivascular rim and rosette pattern. Intramedullary lesions typically extend over several spinal levels, involve both gray and white matter, and are often necrotic. Gliosis, cystic degeneration, cavitation, and atrophy are typical of chronic spinal cord and optic nerve and chiasmal lesions. A marked loss of AQP4 immunoreactivity is observed in all

TABLE 71.8 Classic Presentations of Neuromyelitis Optica Spectrum Disorder

Symptom	Sign	Localization
Blurred vision Pain with eye movement	Relative apparent pupillary defect Red desaturation[a]	Optic nerve
Limb weakness Bladder/bowel dysfunction	Paraparesis or monoparesis	Spinal cord
Intractable nausea, vomiting or hiccups	NA	Area postrema

[a]Red desaturation: decreased ability to perceive the color red.

NMOSD-demyelinating lesions regardless of location, stage, or degree of necrosis and occurs in regions with extensive vasculocentric immunoglobulin and complement deposition.

AQP4 autoantibodies are not detected in a minority of patients who meet clinical criteria for NMOSD. These individuals may have autoantibodies against MOG. Anti-MOG syndromes are described further in the following text.

Diagnosis

Clinical Manifestations

Patients typically experience frequent and severe exacerbations of optic neuritis or myelitis interspersed with periods of remissions. See **Table 71.8** for a description of classic NMOSD presentations. Disability typically accumulates with successive exacerbations and does not follow a slowly progressive course, in contrast to MS.

Optic neuritis (unilateral or bilateral) and/or longitudinally extensive transverse myelitis (more than three spinal segments) are the most common presenting symptoms of NMOSD, and symptoms may be severe. Disease outside of the spinal cord and optic nerves occurs in 10% to 15% of patients. These symptoms may include vomiting, intractable hiccups, narcolepsy, facial weakness or numbness, diplopia, vertigo, dysarthria, trigeminal neuralgia, tremor, ataxia, hearing loss, hemiparesis, and encephalopathy. There is often improvement after the first attack, but a second episode occurs in 60% of patients within 1 year and in 90% within 3 years.

NMOSD can be diagnosed in patients who exhibit at least one core clinical characteristic (**Table 71.9**) and have a positive blood test for AQP4, when other diagnoses have been excluded. When patients are seronegative for AQP4, they must exhibit at least two core clinical characteristics occurring as a result of one or more clinical episodes. In this situation, at least one of the core clinical characteristics must be optic neuritis, longitudinally extensive transverse myelitis, or area postrema syndrome. Additional MRI characteristics apply to the diagnosis of seronegative cases.

Radiologic Manifestations

Brain MRIs are normal in 55% to 84% of patients with NMOSD, apart from sequelae of optic neuritis. Over time, however, brain lesions may develop in up to 85% of patients. These lesions tend to occur in the hypothalamus, thalamus, brainstem, and around the third and fourth ventricles, which are all sites of high AQP4 expression. Large lesions in the cerebral hemispheres are occasionally observed. Optic nerve lesions may be longitudinally extensive and involve the optic chiasm or optic tracts.

TABLE 71.9 Neuromyelitis Optica Diagnostic Criteria[a]

Core clinical characteristics:

1. **Optic neuritis**
2. **Acute myelitis**
3. **Area postrema syndrome: episode of acute nausea, vomiting or unexplained hiccups**
4. Acute brainstem syndrome
5. Symptomatic narcolepsy or acute diencephalic syndrome with NMOSD-typical diencephalic brain lesions on MRI
6. Symptomatic cerebral syndrome with NMOSD-typical brain lesions on MRI

MRI criteria for AQP4-negative or AQP4-unknown cases

1. Acute optic neuritis
   - Brain MRI must be normal or with only nonspecific white matter lesions
   - *Or* optic nerve MRI showing T2 hyperintense or T1 gadolinium-enhancing lesion extending over one-half the optic nerve length or involving the optic chiasm
2. Acute myelitis
   - Spinal MRI must demonstrate intramedullary lesion extending ≥3 contiguous segments
   - *Or* ≥3 contiguous segments of focal spinal cord atrophy and a clinical history of myelitis
3. Area postrema syndrome
   - Brain MRI must show dorsal medulla/area postrema lesions.
4. Acute brainstem syndrome
   - Brain MRI must show periependymal brainstem lesions.

Abbreviations: AQP4, aquaporin 4 autoantibodies; MRI, magnetic resonance imaging; NMOSD, neuromyelitis optica spectrum disorder.

[a]Adapted from Wingerchuk DM, Banwell B, Bennett JL, et al. International consensus diagnostic criteria for neuromyelitis optica spectrum disorders. *Neurology*. 2015;85(2):177-189.

Such brain lesions may occasionally fulfill McDonald criteria for MS; however, in the presence of AQP4 autoantibodies, the diagnosis of NMOSD is a better descriptor of the clinical syndrome.

In the setting of myelitis, spinal cord MRI is the most sensitive diagnostic test for NMO. Longitudinally extensive T2 lesions involving more than three vertebral segments, and frequently more than six, are characteristic of NMO (see **Fig. 71.8**). Spinal lesions are frequently edematous, occupying the gray matter of the central cord and demonstrating contrast enhancement during an acute episode. The MRI lesions frequently become less radiologically prominent during remissions, but spinal cord atrophy may be seen. Preferential central gray matter involvement as well as gadolinium enhancement and spinal cord swelling are common. Lesions often become smaller over weeks to months, either spontaneously or in response to corticosteroids, and spinal cord atrophy may develop. Although characteristic of NMO, longitudinally extensive lesions are not specific to the disease and are also seen in a variety of illnesses, including infectious and other inflammatory diseases, as well as in patients with vascular lesions and tumors (**Figs. 71.9** and **71.10**).

Biomarkers

Anti-AQP4-IgG is detected in approximately 85% of patients with NMOSD. The antibody has 72% to 91% sensitivity and 100% specificity for the diagnosis of NMOSD. The minority of patients who are AQP4 seronegative may have a different epidemiology and disease course.

Although not part of NMO diagnostic criteria, CSF analysis may be informative in some patients and useful for excluding alternative diagnoses. When examined within 4 weeks of the onset of an exacerbation, CSF typically reveals a mild pleocytosis

FIGURE 71.9 Neuromyelitis optica spectrum disorder patient with an acute myelitis. **A:** Sagittal T2-weighted image of the cervical spine shows an intramedullary lesion extending from C1 to T1 accompanied by spinal cord swelling. A second lesion is seen in the visualized portion of the upper thoracic spine. **B:** A follow-up magnetic resonance imaging 8 months later shows marked improvement.

(this may be monocytic, lymphocytic, or neutrophilic) and an elevated protein. Up to 35% of patients have WBC of ≥50/μL. Oligoclonal bands are typically absent (in 70%-85% of cases) in contrast to MS.

Non–organ-specific autoantibodies, especially antinuclear or extractable nuclear antibodies, are frequently detected in the serum of patients with NMOSD. Rheumatoid factor or double-stranded DNA antibodies may also be observed. Patients with NMOSD often exhibit concurrent systemic autoimmune diseases, such as Sjögren, myasthenia, autoimmune thyroiditis, and sarcoidosis.

Management

The NMO exacerbations are usually treated with IV methylprednisolone 1 g daily for 5 to 7 days. Plasma exchange, which is indicated for severe exacerbations that do not respond to high-dose IV corticosteroids, results in functional improvement in up to 60% of patients. Early incorporation of plasma exchange improves outcomes.

Recently, three phase 3 clinical trials of NMOSD have been completed and demonstrated efficacy in relapse reduction. These trials tested the complement inhibitor eculizumab, the IL-6 receptor inhibitor, satralizumab, and the B-cell depleting monoclonal antibody, inebilizumab. Eculizumab significantly decreased the risk of relapse in AQP4-positive patients compared to those taking placebo (study drugs were administered as add-ons to preexisting oral immunomodulators during the trial) LEVEL 1[24] and it was FDA approved for treating AQP4-positive NMOSD in 2019. Inebilizumab and satralizumab also significantly reduced the risk of an NMOSD attack compared to placebo LEVEL 1.[25,26] Rituximab, azathioprine, and mycophenolate are also commonly used off-label to treat NMOSD. Interferon-β, glatiramer acetate, and fingolimod appear to worsen the course of NMOSD, underscoring the importance of correctly distinguishing NMOSD from MS.

Therapies aimed at treating spasticity, pain, sphincter dysfunction, and other chronic NMOSD symptoms play an integral part in patient management and are similar to the ones described earlier for treating daily symptoms associated with MS.

FIGURE 71.10 Longitudinally extensive spinal cord lesions in other diseases. Sagittal **(A)** and axial **(B)** T2-weighted images of the cervical spine show an intramedullary lesion predominantly involving gray matter from C2 to C6 in a patient with neuroborreliosis. **C:** A sagittal T2-weighted image of the cervical spine shows an intramedullary lesion extending from C4 to T1 and spinal cord swelling at C5-C6 in a patient with neurosarcoidosis. **D:** A sagittal T2-weighted image of the distal spinal cord and conus medullaris shows increased signal in the lower thoracic spinal cord, a small hemorrhage *(arrow)* at the conus tip, and numerous flow voids along the posterior spinal cord surface in a patient with a dural arteriovenous fistula.

Outcomes

The prognosis of untreated NMOSD is poor, with the potential for profound visual loss and paresis developing early in the course of the disease as a result of incomplete recovery from attacks. Myelopathic pain, spasticity, dysesthesias, and tonic spasms as well as bowel and bladder dysfunction are common. In a cohort of patients seen at the Mayo Clinic, 60% were legally blind in at least one eye and more than 50% had either mono- or paraplegia within 8 years of disease onset. The 5-year survival rate was only 68%, and all deaths were attributable to respiratory failure from acute intramedullary cervical spine lesions.

Treated cases of NMOSD appear to have a far better prognosis, although the dearth of clinical trial data makes this difficult to quantify. In one randomized, controlled phase 3 trial, relapses occurred in 3% of patients treated with eculizumab (sometimes in combination with additional immunotherapies including azathioprine and mycophenolate) compared to 43% of patients treated with placebo (sometimes in combination with additional immunotherapy, as earlier). In another trial, 12% of patients had an attack on inebilizumab compared with 39% of placebo-treated patients.

ANTI–MYELIN OLIGODENDROCYTE GLYCOPROTEIN SYNDROMES

Anti-MOG antibodies have recently been identified as mediating a distinct set of neurologic syndromes. Although these antibodies can be detected in a subset of seronegative NMOSD patients, the clinical spectrum for anti-MOG disease is far broader than that of AQP4-mediated disease.

Epidemiology

No large-scale epidemiologic studies of anti-MOG syndromes have been performed. Currently available data are based on small case series. Overall incidence is estimated at 0.16 per 100,000 individuals. There does not appear to be a sex predominance in anti-MOG disease; affected individuals are approximately 50% female. Caucasians represented 78% to 90% of cases. Anti-MOG syndromes appear to be more common in pediatric patients (estimated incidence of 0.31 per 100,000 compared to 0.13 per 100,000 in adults), and they may develop in the setting of recent infections or vaccines.

Pathobiology

Patients with anti-MOG syndromes demonstrate demyelination without the astrocytic pathology observed in AQP4-positive disease. Anti-MOG antibodies are felt to mediate pathology based on in vitro studies and animal models of disease.

Diagnosis

Clinical Manifestations

Anti-MOG syndromes may mimic AQP4-positive NMOSD by presenting with optic neuritis or longitudinally extensive transverse myelitis. Some patients have only relapsing optic neuritis, and many patients diagnosed with chronic relapsing inflammatory optic neuritis were discovered to have anti-MOG antibodies once testing became available. In addition to optic neuritis and transverse myelitis, patients with anti-MOG disease may exhibit encephalitis, ADEM, or other atypical demyelinating syndromes. The most common clinical manifestation of anti-MOG syndromes are optic neuritis for adults and ADEM for children.

Diagnostic Criteria

The diagnosis of an anti-MOG syndrome is based on positive serologic autoantibody testing in a patient presenting with suggestive neurologic symptoms.

Biomarkers

Anti-MOG antibodies are detected in the serum using cell-based assays. A CSF testing may reveal mild pleocytosis. Oligoclonal bands are typically negative.

Management

Chronic immunosuppression is not always necessary because anti-MOG syndromes were reported to be monophasic in 41% to 70% of cases. When patients convert from seropositive to seronegative for anti-MOG antibodies, a monophasic course is more likely.

There are no randomized controlled trials of anti-MOG disease. In the acute setting, patients are treated with steroids and/or plasmapheresis, similar to MS or NMOSD exacerbations. Once the disease has been determined to be relapsing, immunomodulators such as rituximab, mycophenolate, azathioprine, and IVIG have been used. Mitoxantrone and natalizumab have failed to reduce relapses in small studies of patients with anti-MOG disease.

Transverse Myelitis 72

Eoin P. Flanagan and Brian G. Weinshenker

KEY POINTS

1. Transverse myelitis (TM) is a clinical syndrome of acute or subacute myelopathy. It is broadly categorized as disease-associated or idiopathic, but it has a broad differential diagnosis. Many noninflammatory disorders can mimic TM, including vascular, toxic/metabolic, and neoplastic myelopathies.
2. The time course of development of neurologic symptoms is among the most important clues to the etiology of a myelopathy. The onset to nadir (maximal deficit) in TM is defined as being between 4 hours and 21 days. Apoplectic onset suggests spinal cord infarction, whereas progression beyond 21 days should raise suspicion for an alternative etiology, such as neoplasm, sarcoidosis, or dural arteriovenous fistula.
3. The presence of longitudinally extensive TM with a sagittal T2 hyperintense lesion extending three or more vertebral segments should prompt assessment of the blood biomarkers aquaporin-4 immunoglobulin G (IgG) and myelin oligodendrocyte glycoprotein-IgG, which are associated with this radiologic finding, and may lead to a diagnosis of an antibody-mediated TM.
4. Careful scrutiny of the gadolinium enhancement pattern on magnetic resonance imaging of TM lesions may provide critical clues to the underlying cause.
5. Acute treatment of TM is initially with high-dose intravenous steroids but in those with a severe residual deficit despite steroids, plasma exchange for 5 to 7 sessions is recommended.
6. A TM may be monophasic or the presenting manifestation of a relapsing disease (eg, multiple sclerosis or neuromyelitis optica), and ancillary testing with brain magnetic resonance imaging, blood biomarkers, and cerebrospinal fluid analysis can help distinguish monophasic disease from those with a relapsing disease.

INTRODUCTION

Transverse myelitis (TM) is a clinical syndrome characterized by acute or subacute myelopathy accompanied by inflammation of the spinal cord. The term *transverse* is based on the sensory level that is clinically detected in many patients, but not all cases of TM are associated with inflammation across the entire cross-section of the spinal cord as the name suggests, and partial TM with inflammation extending across only a portion of the spinal cord is well recognized. Furthermore, many patients do not have "transverse" pathology but pathology that extends over the long axis of the spinal cord and may affect most of the spinal cord. The TM has traditionally been divided into disease-associated and idiopathic etiologies (Table 72.1). Disease-associated TM may occur in the context of a monophasic or relapsing central nervous system (CNS) inflammatory demyelinating disease (IDD) (eg, multiple sclerosis [MS]), neurosarcoidosis, or an infection (eg, varicella zoster virus myelitis) in which case myelitis is monophasic. New autoantibody biomarker discoveries of CNS IDDs (eg, aquaporin-4 immunoglobulin G [AQP4-IgG] accompanying neuromyelitis optica spectrum disorder [NMOSD]) and improved recognition of the neuroimaging features of myelopathies have transformed the classification of

TABLE 72.1 Transverse Myelitis Etiologies

Disease-Associated Transverse Myelitis	Clinical/MRI Clues
Inflammatory Demyelinating Disease	
• Multiple sclerosis	Short-peripheral T2 lesions in dorsal/lateral columns
• Aquaporin-4 antibody seropositive NMOSD	Longitudinally-extensive T2-lesion
• Myelin oligodendrocyte glycoprotein (MOG) antibody disease	Long or short T2-lesion; conus involvement; nonenhancing
• Acute disseminated encephalomyelitis	Coexisting deep gray brain lesions
Inflammatory, Confirmed Etiology	
• Spinal cord sarcoidosis	Linear dorsal subpial/trident enhancement
• Connective tissue disease associated (Behçet, lupus, Sjögren's syndrome)[a]	Systemic features of connective tissue disease
• Paraneoplastic	Known cancer; cancer risk factors; tract-specific lesion, especially gadolinium enhancing
• Immune checkpoint inhibitor associated	Recent use of checkpoint inhibitor
Infectious	
• Bacterial (Lyme, syphilis, tuberculosis)	Recent tick bite/rash; high-risk behavior
• Viral (VZV, HSV 1, HSV 2 [may be associated with lumbar myeloradiculitis, Elsberg syndrome], CMV, West Nile, enterovirus-associated acute flaccid myelitis; HIV)	Zoster rash, genital herpes, endemic region for enterovirus/West Nile virus; high-risk behavior
• Parasitic (schistosomiasis)	Endemic region
Idiopathic Transverse Myelitis	

Abbreviations: CMV, cytomegalovirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; MRI, magnetic resonance imaging; NMOSD, neuromyelitis optica spectrum disorder; VZV, varicella zoster virus.
[a]Can be due to coexisting aquaporin-4 immunoglobulin G seropositive NMOSD.

many TM from "idiopathic" to "disease-associated." Many other disorders (eg, spinal cord infarct) can mimic TM (**Table 72.2**). The broad differential diagnosis (see **Tables 72.1** and **72.2**) requires clinicians to scrutinize the acuity of onset, neuroimaging characteristics, cerebrospinal fluid (CSF) findings, and blood biomarkers to reach the correct diagnosis. Once a diagnosis of TM is reasonably suspected (ie, compression and infarction are excluded), acute treatment is administered even before an etiology is determined to reduce disability from the TM attack. If a disease-associated etiology is identified (eg, MS), chronic maintenance treatments may prevent future attacks targeting the spinal cord or other parts of the CNS.

TABLE 72.2 Mimics of Transverse Myelitis

Etiologies Stratified by Onset	Clues to Diagnosis
Acute	
Vascular	
• Spinal cord infarct (anterior or posterior spinal artery)	Vascular risk factors
• Fibrocartilaginous embolism	Valsalva, disc adjacent to lesion
• Hematoma (hematomyelia, epidural hematoma)	Bleeding diathesis, trauma
Structural/trauma	
• Surfer's myelopathy	Novice surfer
• Spinal cord contusion	Recent trauma
Chronic Progressive (May Have Subacute Onset/Worsening)	
Vascular	
• Dural arteriovenous fistula	Clinical worsening after exertion or steroids
• Cavernous malformation/other AVM	"Popcorn" appearance[a]
Inflammatory or demyelinating	
• Progressive solitary sclerosis	Single MS-lesion in lateral columns, pyramids of medulla
• Primary progressive MS	Multiple short T2 lesions in cord
• Spinal cord sarcoidosis	Milder deficit despite large lesion
• Paraneoplastic	Known cancer, smoking
Infectious	
• Bacterial (syphilis, tuberculosis)	High-risk behavior, endemic region
• Viral (HIV, HTLV-1)	High-risk behavior, endemic region, dorsal/lateral column signal abnormality
Neoplastic	
• Primary spinal cord gliomas (astrocytoma, ependymoma)	Prior radiation, expansile, mass effect, cap sign[b]
• Primary intramedullary spinal cord lymphoma	Expansile lesion, persistent enhancement (>3 mo), steroid responsive, immunosuppressed
• Metastatic disease (intramedullary, extramedullary compressive)	Known solid organ cancer
Structural	
• Spondylotic myelopathy	Known neck osteoarthritis
Hereditary	
• Adrenomyeloneuropathy	Neuropathy, progressive cord atrophy, adrenal involvement
• HSP	Spasticity disproportionate to weakness, progressive spinal cord atrophy
• Mitochondrial disorders (eg, *DARS2* gene)	Dorsal/lateral signal abnormality, ↑lactate
• Other genetic	
Toxic/metabolic	
• Nutritional deficiency (vitamin B12, copper)	Gastric bypass, zinc supplements, malabsorption
• Toxic (intrathecal methotrexate, heroin)	Toxic exposure
Iatrogenic	
• Radiation	Prior radiation exposure

Abbreviations: ↑, increased; AVM, arteriovenous malformation; HIV, human immunodeficiency virus; HSP, hereditary spastic paraplegia; HTLV-1, human T-lymphotropic virus type 1; MS, multiple sclerosis.

[a]Popcorn appearance—mixed intensity at the center of the lesion from vascular components with a T2 hypointense rim from blood products.

[b]A cap of T2 hypointensity secondary to hemosiderin is present at the top or bottom of the lesion.

EPIDEMIOLOGY

TM can affect patients of any age, both men and women. Depending on the etiology, the ratio of affected men to women and the mean age can vary greatly. Children are particularly predisposed to myelin oligodendrocyte glycoprotein (MOG) antibody disease and the acute flaccid myelitis associated with enterovirus infection. TM occurring as a manifestation of MS (female-to-male ratio 2:1) or AQP4-IgG seropositive NMOSD (female-to-male ratio 9:1) disproportionately affects women. MS is more common in Caucasians and in regions further from the equator, whereas those of African descent are particularly predisposed to AQP4-IgG seropositive NMOSD and sarcoidosis. The incidence of idiopathic TM is 6.1 to 8.6 per million person-years, but when disease-associated TM cases are included, the incidence increases to 24.6 per million person-years. Epidemic outbreaks of acute flaccid myelitis associated with enterovirus infections also impact the incidence.

PATHOBIOLOGY

The pathology of TM is dependent on the underlying disease causing TM and may include disease-specific findings, such as granulomas in neurosarcoidosis and selective loss of AQP4 immunoreactivity in nonnecrotic tissue. The pathology of TM includes variable degrees of tissue and perivascular inflammation, demyelination, and axonal injury and occasionally necrosis. Many conditions that lead to myelitis may target multiple CNS structures (eg, MS and sarcoidosis) and extra CNS structures (eg, sarcoidosis). In NMOSD, AQP4-IgG targets the dominant water channel of the CNS, AQP4, the expression of which is greatest in optic nerve and spinal cord, the two structures of the CNS that are predominantly targeted in this condition. The AQP4-IgG results in severe necrosis associated with markers of complement activation, consistent with current understanding of pathogenesis of this condition (see Chapter 73).

DIAGNOSIS

Clinical Presentation

The clinical approach to myelopathy is summarized in Figure 72.1. TM may be preceded by an infection or vaccination (particularly for MOG-IgG) while preceding nausea, vomiting or hiccups suggest concomitant area postrema involvement of AQP4-IgG positive NMOSD.

Patients with TM typically present with subacute numbness often accompanied by a sensory level on the torso, weakness, neurogenic bowel, neurogenic bladder, or sexual dysfunction. The time course of development of neurologic symptoms is among the most important clues to the etiology of the syndrome. The onset to nadir (maximal deficit) in TM is defined as being between 4 hours and 21 days. More rapid onset of severe symptoms (paraplegia/quadriplegia), sometimes followed by rapid spontaneous improvement, suggests spinal cord ischemia or infarction instead of myelitis, whereas progression of symptoms beyond 21 days is characteristic of sarcoidosis or a nonmyelitis alternative etiology for myelopathy (eg, spondylosis, dural arteriovenous fistula, tumor). Mixed upper and lower motor neuron findings (eg, inverted brachioradialis reflex) may suggest a compressive etiology with root damage at the site of most severe stenosis and myelopathy below that from the accompanying cord compression. Worsening symptoms and signs with exertion, stepwise worsening, or exacerbation with corticosteroids (resulting from transient fluid retention and worsened venous engorgement) strongly suggest dural arteriovenous fistula.

Lhermitte symptom (a usually painless electrical or vibrating sensation down the spine and occasionally into the extremities precipitated by neck flexion), paroxysmal painful tonic spasms (involuntary [usually flexor] contractions lasting seconds to minutes following a TM episode and responsive to low-dose carbamazepine), or McArdle sign (increased pyramidal weakness with neck flexion) suggests CNS demyelinating disease as the cause of TM. A sensory level on the torso, upper motor neuron pattern weakness, hyperreflexia, spasticity, and a Babinski sign suggest spinal cord localization. Spinal shock can occur in acute TM and result in flaccid paraplegia with hypo- or areflexia, incorrectly suggesting a peripheral nervous system etiology, such as acute inflammatory demyelinating polyneuropathy. When bowel and bladder function are affected severely, the localization is usually the spinal cord, and not peripheral nervous system. However, a concomitant cauda equina syndrome may occur in association with a caudal myelitis in individuals with Elsberg syndrome, a lumbar myeloradiculitis characteristically accompanying herpes simplex virus type 2 genital infection. Myeloradiculitis may also occur in the setting of cytomegalovirus-associated cauda equina syndrome often occurring in patients with underlying immunosuppression, such as human immunodeficiency virus infection.

Traditionally, TM has been classified accordingly: partial TM, which involves only a portion of the spinal cord often with unilateral sensory or motor symptoms/signs or with sensory *or* motor, but not both, and mild impairment that is typical of MS; complete TM, which involves the entire cross-section of the spinal cord with bilateral symptoms/signs and severe disability that lead to central and usually "longitudinally extensive TM" with pathology extending over long rostrocaudal segments of the spinal cord, characteristic of AQP4-IgG seropositive NMOSD. However, the clinical distinction between partial and complete myelitis does not consistently correlate with pathology and etiology. Other considerations such as the interval between onset to nadir, severity of the clinical deficit, and length of the T2 hyperintense lesion on magnetic resonance imaging (MRI) spine are more useful indicators of etiology (see Tables 72.1 and 72.2). Coexisting clinical features of a connective tissue disorder (lupus, Sjögren's syndrome, or anti-phospholipid syndrome) should prompt assessment of AQP4-IgG because NMOSD commonly coexists with these disorders. Oral and genital ulcers are a clue to Behçet, whereas concomitant genital herpes infection can suggest Elsberg syndrome.

MAGNETIC RESONANCE IMAGING

An MRI of the cervical and thoracic spine with and without gadolinium is recommended to both exclude an extrinsic compressive cause and to identify intrinsic spinal cord abnormalities that accompany TM (Fig. 72.2) but also mimics of TM (Fig. 72.3). The pattern of gadolinium enhancement is particularly useful in discriminating between these causes. The MRI characteristics of spinal cord lesions in TM subtypes and its common mimics are outlined in Table 72.3.

FIGURE 72.1 Transverse myelitis (TM) diagnostic and treatment algorithm. Abbreviations: ADEM, acute disseminated encephalomyelitis; AIDP, acute inflammatory demyelinating polyradiculoneuropathy; AQP4, aquaporin 4; C, cervical; CSF, cerebrospinal fluid; DMTs, disease-modifying therapies; GAD, glutamic acid decarboxylase; GFAP, glial fibrillary acidic protein; IgG, immunoglobulin G; IVMP, intravenous methylprednisolone; MOG, myelin oligodendrocyte glycoprotein; MRI, magnetic resonance imaging; MS, multiple sclerosis; NMOSD, neuromyelitis optica spectrum disorder; PLEX, plasma exchange; T, thoracic.

FIGURE 72.2 Examples of disease-associated transverse myelitis. **A:** Multiple sclerosis myelitis with a short T2 hyperintense lesion (**A1**, *arrow*) in the right lateral column on axial sequences (**A2**, *arrow*) associated with ringlike on T1-weighted sequences following gadolinium administration (**A3** and **A4**, *arrows*). **B:** Aquaporin-4 immunoglobulin G (IgG) seropositive neuromyelitis optica spectrum disorder reveals a longitudinally extensive (more than three vertebral segments) T2 hyperintense lesion (**B1**, *arrows*) that was centrally located within the spinal cord on axial sequences (**B2**, *arrow*) and enhanced following gadolinium administration (**B3**, *arrows*) in a ringlike pattern on axial T1-weighted sequences (**B4**, *arrow*). **C:** Myelin oligodendrocyte glycoprotein–IgG myelitis with a longitudinally extensive T2 hyperintense lesion (**C1**, *arrows*) that is restricted to gray matter on axial sequences in an H pattern (**C2**, *arrow*) and without gadolinium enhancement (**C3** and **C4**, *arrow*). **D:** Spinal cord sarcoidosis revealed a longitudinally extensive T2 hyperintense lesion (**D1**, *arrows*) that was central on axial sequences (**D2**, *arrow*) and had accompanying linear dorsal subpial enhancement following gadolinium administration extending over multiple vertebral segments (**D3** and **D4**, *arrows*).

Cerebrospinal Fluid

Pleocytosis, usually lymphocytic, and increased protein are typically detected in TM, and their absence should raise some concern about the accuracy of the diagnosis. CSF unique oligoclonal bands are found in approximately 85% of patients with MS but in less than a quarter of patients with AQP4-IgG and less than 15% of MOG-IgG-associated TM. Normal or mildly elevated white blood cell count (<50/μL) is typical of MS, but elevations above 50/μL should raise suspicion for alternative etiologies, including NMOSD or sarcoidosis. Absence of CSF indicators of inflammation should raise concern for a noninflammatory cause. High protein with normal cell count (albuminocytologic dissociation) may indicate a spinal block from tumor or spondylosis or may suggest an alternative cause such as Guillain-Barré syndrome. CSF Gram stain, smear cultures (bacterial, fungal, mycobacterial), and other infectious testing can be useful to assess for infectious etiologies including viral polymerase chain reaction and serology (see Table 72.1). CSF cytology and flow cytometry are useful when a neoplastic myelopathy is a consideration.

Biomarkers of Transverse Myelitis

AQP4-IgG is a highly specific (>99%) biomarker of NMOSD. Cell-based immunoassays using target cells that have been transfected with recombinant antigen yield optimal sensitivity and specificity by presenting conformationally intact antigen as the substrate in the assay. TM associated with AQP4-IgG is more severe than MS frequently resulting in an inability to ambulate unaided. Detection of AQP4-IgG in a patient with TM predicts that the patient will relapse. MOG-IgG is a recently discovered antibody biomarker of TM and similarly is best detected in serum using a cell-based assay. MOG-IgG myelitis tends to be more

FIGURE 72.3 Longitudinally extensive myelopathies that mimic transverse myelitis. A patient with an ischemic myelopathy has a pencil-like longitudinally extensive T2 hyperintense lesion extending three vertebral segments in the anterior part of the cervical cord (**A1**, *arrows*); axial images show a typical owl/snake eye pattern (**A2**, *arrows*). A patient with cervical spondylotic myelopathy is shown with a longitudinally extensive spindle-shaped T2 hyperintensity (**B1**, *arrows*) with associated moderate spondylotic changes and spinal cord swelling. A transverse band of pancake-like enhancement at the center of the T2 hyperintensity is noted (**B2**, *arrows*), which on axial postgadolinium T1 images is characteristically located in the periphery of the spinal cord and spares central gray matter (**B3**, *arrows*). A dural arteriovenous fistula is shown with a typical longitudinally extensive lesion (more than three vertebral segments) in the thoracic cord extending to the conus (**C1**, *arrows*) with accompanying flow voids noted in the dorsal cord (**C1**, *arrowheads*). On postgadolinium images, enhancing veins dorsal to the cord are seen (**C2**, *arrowheads*). An ependymoma is shown with a longitudinally extensive expansile lesion, which is mixed T2 hyperintense and T2 isotense (**D1**, *arrows*) with evidence of syringohydromyelia (**D1-D4**, *arrows*) and a "cap sign" with a T2 hyopintense hemosiderin rim (**D1**, *arrowhead*) all typical of an ependymoma. (Reprinted from Flanagan EP. Autoimmune myelopathies. *Handb Clin Neurol*. 2016;133:327-151; Figure 5.)

severe than attacks of MS but is associated with better recovery than attacks of AQP4-IgG TM.

Paraneoplastic myelitis is a rare condition that can present as an acute, subacute, or chronic myelopathy and may be associated radiologically with corticospinal or other tract-specific signal abnormality, occasionally with gadolinium enhancement. Various autoantibodies have been associated with this syndrome, including collapsin response–mediator protein 5 IgG (CV2) and amphiphysin-IgG, which are the two most commonly encountered antibodies; small-cell lung and breast the most frequent associated neoplasms.

Other Investigations

In the setting of acute flaccid myelitis, nasopharyngeal swabs for viral culture and serologic testing of serum and CSF assessment for enterovirus D68 or other enterovirus serotypes is appropriate. Serology for other infections (see **Table 72.1**) should be considered in TM and recommendations and may vary by region depending on epidemiologic considerations.

Serologic markers for connective tissue disorders should be assessed and include antinuclear antibody, SSA/SSB, double-stranded

TABLE 72.3 Magnetic Resonance Imaging Findings in Transverse Myelitis and Its Mimics

	Spinal Location	T2 Lesion Number	Sagittal T2 Length (Short: <3 Vert Segments; Long: ≥3 Vert Segments)	Axial T2	Post-Gad Pattern	Other Feature(s)
Disease-Associated TM						
MS	C or T	Multiple	Short	Peripheral (dorsal or lateral columns)	Ringlike, homogeneous	
AQP4-IgG	C or T	Single	Long 85%; short 15%;	Central (gray and white matter)	Ringlike, patchy	Bright spotty T2[a]
MOG-IgG	C or T	Multiple	Long 70%; short 30%	Central (30% gray matter restricted/ H sign[b]])	Faint or no enhancement	Conus
Sarcoidosis	C or T	Single	Usually long	Central	Dorsal subpial[c] or axial trident[d]	
Acute flaccid myelitis	C or T	Single	Long or short	Central gray/H sign[a]	Faint or no enhancement	
Paraneoplastic	C or T	Single	Long	Tract-specific signal (dorsal/lateral column)	Tract-specific enhancement (dorsal/ lateral columns)	MRI normal in up to 50%
Elsberg syndrome (HSV-2 or other virus)	L	Single	Short	Central	Variable	Cauda equina enhancement
Most Common Mimics of TM						
Spondylosis	C	Single	Long or short	Central owl eye[e]	Sag: Pancake-like[f] Axial: circumferential sparing gray matter	Cervical canal stenosis, other spondylotic changes
Spinal cord infarct	C or T	Single	Long or short	Owl eye[e]	Linear strip[g] Owl eye[e]	Diffusion restriction; vertebral body infarct; adjacent artery dissection
Dural AVF	T	Single	Long	Central	Patchy, missing piece,[h] enhancing large veins; 40% no enhancement	Flow voids dorsal to cord
Nutritional (Vitamin B12, copper)	C or T	Single	Long	Tracts (dorsal/lateral columns)	None	
Intramedullary metastases	C or T	Single or multiple	Long or short	Central or peripheral	Rim and flame[i]	

Abbreviations: AQP4, aquaporin-4; AVF, arteriovenous fistula; C, cervical; Gad, gadolinium; HSV-2, herpes simplex virus type 2; IgG, immunoglobulin G; L, lumbar; MOG, myelin oligodendrocyte glycoprotein; MRI, magnetic resonance imaging; MS, multiple sclerosis; T, thoracic; TM, transverse myelitis; Vert, vertebral.
[a]Very bright T2 hyperintensity of similar consistency to cerebrospinal fluid (syrinx-like) spotted within less bright T2 hyperintense lesion.
[b]T2-signal abnormality restricted to gray matter on axial image forming an H.
[c]Parenchymal enhancement extending inward from the dorsal surface of the cord.
[d]Dorsal subpial enhancement combined with central canal enhancement creates a three-pronged appearance on axial sequences with the appearance of a trident.
[e]Bilateral anterior horn cell involvement with the appearance of owl eyes (or snake eyes).
[f]Transverse band of enhancement in which the width is greater than or equal to the height that appears squashed like a "pancake."
[g]A linear strip of enhancement along in the anterior cord on sagittal images.
[h]Area of absent enhancement within a long segment of homogeneous enhancement appearing as if the enhancement has a "missing piece."
[i]A rim of enhancement around a less enhancing central region of milder enhancement with a flame appearance at the top or the bottom of the lesion.

DNA, and C3 and C4 complement. Computed tomography chest or ^{18}F-fluorodeoxyglucose positron emission tomography can be considered to detect evidence for systemic sarcoidosis or for a neoplasm in suspected neoplastic or paraneoplastic myelopathy. Testing for other mimics of TM may also be considered (see Table 72.2).

MANAGEMENT

The initial treatment for acute TM associated with CNS demyelinating disease (see Table 72.1) is 1 g of intravenous methylprednisolone once daily for 3 to 5 days. In patients with prominent residual deficits despite high-dose steroids, a course of plasma exchange (PLEX) for five to seven sessions is recommended. A randomized sham-controlled double-masked study of PLEX in acute CNS IDD (including TM) patients who failed to recover with corticosteroids experienced moderate or greater recovery 9 fold more often (45% vs 5%) with PLEX than the sham treatment LEVEL 1.[1] Treatment of infectious TM is aimed at the underlying cause (see Table 72.1), but for some infections (acute flaccid myelitis associated with enterovirus D68), no effective treatments

are available and symptomatic treatment is the mainstay. Rehabilitation with physical and occupational therapy are also essential strategies to train patients to compensate for their neurologic impairments and to overcome disability.

OUTCOME

It is important to consider both recovery from the individual attack of TM and to consider the risk of relapse, either with another episode of TM or another neurologic syndrome, such as optic neuritis. The prognosis of both outcomes varies according to the specific diagnosis of the TM.

Recovery of function following MS- and MOG-IgG–associated TM is better than for AQP4-IgG–associated TM. Approximately, a quarter to one-third of TM episodes will have a poor outcome often defined as a modified Rankin score of ≥3 at last follow-up. The presence of severe disability at presentation, complete TM, flaccid paraplegia, motor and urinary symptoms, and peripheral nervous system involvement predict poor outcome.

In terms of recurrence risk, patients with partial TM or MRI lesions characteristic of MS are at risk of developing MS. The risk of developing symptoms that lead to diagnosis of MS within 5 years after partial TM may be stratified based on findings on brain MRI. Detection of multiple typical MS lesions indicate a high risk (>80%), whereas absence of MS brain lesions indicate low risk (<20%) of developing MS; the presence of positive oligoclonal bands in CSF also predicts a higher risk of developing MS. Therefore, MS disease–modifying medications are often initiated to reduce the risk of future relapses in patients with TM and typical MS brain lesions but not in those without brain lesions who have a low risk of MS relapses. An AQP4-IgG seropositivity accompanying a TM episode is sufficient for a diagnosis of AQP4-IgG seropositive NMOSD. Attack-preventing immunosuppressive treatments are strongly recommended to reduce the risk of future potentially devastating relapses in patients with AQP4-IgG seropositive with an attack of TM (see Chapter 73: NMO spectrum disorder). MOG-IgG seropositivity is associated with risk of future demyelinating events (particularly optic neuritis), but the risk of relapse is less well defined in this situation, and the role of attack prevention treatments after an initial TM remains to be determined; if a patient who is MOG-IgG seropositive relapses, immunosuppression to prevent subsequent attacks would be indicated.

73 Neuromyelitis Optica Spectrum Disorder

Iris Vanessa Marin Collazo and Brian G. Weinshenker

KEY POINTS

1. Neuromyelitis optica spectrum disorder (NMOSD) is a central nervous system inflammatory disease, usually with a relapsing course, that has a particular predilection to cause optic neuritis and transverse myelitis.
2. NMOSD is classified based on whether or not it is associated with antibodies to aquaporin-4 immunoglobulin G (AQP4-IgG). AQP4-IgG–seropositive cases account for approximately 70% of patients.
3. A second autoantibody, myelin oligodendrocyte glycoprotein IgG (MOG-IgG), is associated with 20% to 40% of AQP4-IgG–seronegative cases; the epidemiology and clinical presentation of MOG-IgG–associated disease differs from that associated with AQP4-IgG.
4. Clinical "red flags" that should prompt to consider alternate diagnosis include a progressive course, hyperacute onset, partial myelitis, and detection of oligoclonal bands in cerebrospinal fluid.
5. Management of NMOSD is directed to rescue treatments for acute attacks, primarily corticosteroids and plasma exchange, and maintenance immunotherapies including eculizumab, a complement 5 inhibitor, inebilizumab, an anti-CD19 B cell depleting antibody, satralizumab, and anti-IL6 receptor antibody.

INTRODUCTION

Neuromyelitis optica spectrum disorders (NMOSD) are a family of syndromes, dominated by optic neuritis (ON) and myelitis, but also including a variety of syndromes, mainly affecting the brain but occasionally affecting other organ systems including muscle. Untreated relapses tend to be more severe than those of multiple sclerosis (MS) and may be fatal, primarily due to respiratory failure occurring in the context of cervical myelitis. It is a relapsing-remitting syndrome that was often confused with MS until the start of the 21st century and even its existence as a condition separate from MS was debated. However, recently developed clinical criteria can confidently distinguish NMOSD from MS. Aquaporin-4 immunoglobulin G (AQP4-IgG), an IgG1 autoantibody biomarker first reported in 2004, has now been accepted as a highly specific diagnostic test for this disease in approximately 70% of patients. More recently, in the second decade of the 21st century, a second IgG1 autoantibody, reactive to myelin oligodendrocyte glycoprotein IgG (MOG-IgG), has been associated with NMOSD in between 20% to 40% AQP4-IgG seronegative patients. Roughly 10% to 15% of patients with this syndrome remain seronegative for both of these biomarkers.

Cases of ON and myelitis occurring simultaneously or nearly simultaneously were reported in the mid-19th century, but Eugène Devic (1858-1930) and his student Fernand Gault, whose thesis reviewed 16 additional historic cases, attracted the greatest attention with their published case description in 1894. The disease became known as *Devic disease*, although no formal diagnostic requirements were delineated. Based on characteristics of Devic's description, 20th century dogma required that the patient have simultaneous or nearly simultaneous bilateral ON and myelitis and no further relapse, relapse being considered an indication of MS rather than Devic disease, in order to establish a diagnosis. In the 1990s, proposed criteria were liberalized to allow for unilateral ON and for relapses. Long spinal cord lesions on magnetic resonance imaging (MRI) in the context of acute myelitis were found to be extremely helpful in differentiating myelitis of Devic disease from that of MS. In Japan, a relatively common form of MS, compared to typical or "Western" MS, that similarly targeted the optic nerve and spinal cord preferentially was labeled opticospinal MS.

Investigators at Mayo Clinic collaborated to identify a pattern of immunostaining by serum of patients with this condition that was characteristic of and specific for NMOSD. A year later, they identified AQP4 as the target of the autoantibody by deducing the antigen based on patterns of immunostaining in AQP4 knockout mice and cell lines transfected with AQP4 or vector alone. Immunoprecipitation confirmed the nature of the antigen.

Discovery of myelin oligodendrocyte glycoprotein (MOG) as a target antigen began with studies of a demyelinating antibody and subsequent development of a double knock-in mouse with both T-cell receptor and immunoglobulin reactive to MOG. A high proportion of these transgenic animals spontaneously developed predominant ON and myelitis but lacked AQP4-IgG. Subsequently, patients seropositive for MOG-IgG demonstrated phenotypic characteristics that resembled NMOSD more closely than MS. However, MOG-IgG–associated NMOSD is often clinically and radiologically distinguishable from AQP4-IgG–associated NMOSD. Furthermore, MOG-IgG is more commonly associated with recurrent ON than AQP4-IgG–associated NMOSD and may be associated with other non-NMOSD clinical syndromes including encephalitic syndromes and leukodystrophies.

EPIDEMIOLOGY

Worldwide Distribution/Ethnicity

Descriptions of the epidemiology of NMOSD are limited by its relatively recent recognition as a disease independent of MS. Early reports were based on inadequate diagnostic criteria for classification, and criteria and terminology varied across the world. Indeed, criteria have continued to evolve; recent internationally accepted criteria have increased the frequency of NMOSD almost two fold, primarily by liberalizing the criteria for AQP4-IgG–seropositive disease, which now requires only a single attack for diagnosis. Screening of all diagnosed MS cases in a community typically will yield additional cases of individuals in whom the diagnosis was not considered in the past. With those caveats, the prevalence of NMOSD is approximately 0.5 to 10/100,000 (**Table 73.1**).

In studies with populations of mixed ethnicity, the risk of NMOSD in Africans is higher than in Caucasians, the opposite of what is seen in MS. However, the disease occurs worldwide at similar frequency. Differences in the ratio of MS to NMOSD across the world are mostly explained by variation in the frequency of MS rather than NMOSD.

Predilection for Africans and Asians not seen in those with MOG-IgG–associated NMOSD. NMOSD can manifest at any age. Approximately 4% of AQP4-IgG–seropositive NMOSD occur in children, and 30% present in those who are older than age 50 years; indeed, there are multiple reports of NMOSD onset in octogenarians. The median age of onset of MOG-IgG–associated NMOSD is younger than that of AQP4-IgG–associated NMOSD.

Sex

The ratio of women to men affected by AQP4-IgG–associated NMOSD is approximately 8:1, whereas it is close to 1:1 for MOG-IgG–associated NMOSD.

Familial Occurrence

There are several reports of familial occurrence; approximately 3% of individuals with NMOSD report affected first-degree relatives, which is in keeping with complex genetic inheritance reflecting interaction of multiple genes or genes and environmental causative factors.

Risk Factors

Individuals with AQP4-IgG NMOSD are more likely to have systemic autoimmune disease than unaffected individuals; up to 25% have one or more autoimmune disease, and the spectrum of autoimmune disease with AQP4-IgG–associated NMOSD is very broad. Approximately half of AQP4-IgG NMOSD patients have one or more high-titer autoantibodies, most commonly thyroperoxidase autoantibodies and Sjögren syndrome A and B autoantibodies usually without clinical manifestations of their corresponding autoimmune diseases. However, the converse is not true, and AQP4-IgG is rarely encountered in patients with type 1 diabetes, rheumatoid arthritis, or systemic lupus erythematosus, except when the latter is complicated by myelitis or ON, in which case it likely represents coassociation of systemic lupus and NMOSD. In Caucasians, distinct from MS, HLA DRB1*03 is positively associated with NMOSD, and there is a negative association with DRB1*1501. In populations of mixed ancestry, NMOSD is overrepresented in non-Caucasians by roughly two- to threefold. No other environmental exposure or illness convincingly correlates with disease risk. No risk factors have been associated with MOG-IgG–associated NMOSD.

PATHOBIOLOGY

AQP4-IgG– and MOG-IgG–Mediated Immunopathology

The main characteristic of NMOSD pathogenesis is antibody-mediated, complement-mediated injury resulting from interaction of a pathogenic antibody with its target antigen (**Fig. 73.1**). This has been best characterized for AQP4-IgG–mediated disease and is less clear for MOG-IgG, the pathologic effects of which have been less clear in experimental studies, in part because of lack of affinity for rodent MOG in passive transfer studies. The discussion here therefore concentrates on AQP4-IgG.

AQP4-IgG is generated in the peripheral immune system, and the concentration in blood is far greater than in cerebrospinal fluid (CSF). Therefore, the autoantibody is more sensitively detected in serum than in CSF. It is an IgG1 autoantibody and thus requires CD4 T cells' help in its generation. The nature of the inciting antigen and defects of immunoregulation are considered in the next section. AQP4-IgG is able to circulate for many years before causing clinical disease, as demonstrated by

TABLE 73.1 Epidemiology of Neuromyelitis Optica Spectrum Disorders (Selected Studies)[a]

Country	Year	Incidence/100,000/y (95% CI)	Prevalence/100,000 (95% CI)	Number of Cases Identified (Number AQP4-IgG+)	Approximate Population Studied
Denmark	2011	0.4 (0.3-0.54)	4.4 (3.1-5.7)	42 (26)	1 million
United Kingdom	2013	0.08 (0.03-0.16)	0.72 (0.31-1.42)	13 (11)	1 million
Iran	2014	NA	1.9 (1.6-2.3)	95	4 million
India	2014	NA	2.6	11	400,000
Martinique	2015	7.3 (4.5-10.1)	10 (6.8-13.2)	39 (31)	400,000
United States	2015	0.7 (0.0-2.1)	3.9 (0.8-7.1)	6 (5)	150,000

FIGURE 73.1 Pathophysiology of aquaporin-4 immunoglobulin G (AQP4-IgG)-associated neuromyelitis optica spectrum disorder and therapeutic strategies shown in *red*. AQP4 peptides are recognized by T cells, which then are polarized to a helper T cell 17 phenotype and provide help to B cells that are activated by conformationally intact AQP4 proteins, which then differentiate into plasmablasts that secrete AQP4-IgG; this occurs outside of the central nervous system (top half of the figure). AQP4-IgG circulates in the blood and enters the central nervous system (bottom half of the figure), where it interacts with AQP4 proteins, encoded on chromosome 18, and are expressed on astrocyte end feet that abut blood vessels and the pia mater and leads to complement activation by classical pathway of C1q binding. AQP4 supramolecular aggregates consisting of the M23 isoform decorated on their periphery by M1 isoform are particularly prone to C1q binding and complement activation when they interact with AQP4-IgG. The AQP4 binding may lead to lytic damage due to complement activation or may lead to activation of astrocytes and an inflammatory milieu due to nuclear factor kappa B signaling. Intervention strategies or drugs that are being considered or are in current use are shown in red font where they are thought to act in the pathophysiology of neuromyelitis optica spectrum disorder. Abbreviations: AQP4, aquaporin 4; EAAT2, excitatory amino acid transporter 2; IL-6, interleukin 6; IL-6R, interleukin 6 receptor; M1, M23, dominant isoforms of AQP4; MHC-1, major histocompatibility complex I protein; TcR, T-cell receptor. (Modified from Weinshenker BG, Wingerchuk DM. Neuromyelitis spectrum disorders. *Mayo Clin Proc*. 2017;92[4]:663-679.)

its detection in serum obtained years earlier from individuals who ultimately developed clinical NMOSD (because they had previously developed other autoimmune diseases or had donated blood for purposes of transfusion). The factors leading to a breach of the blood-brain barrier are unclear, but one of the early sites of pathology is the area postrema, which has a relatively permeable blood-brain barrier and is responsible for the symptoms of intractable vomiting and hiccup that are present in a quarter of patients at disease presentation. Experimentally, systemic administration of antibody to generate passively generated pathology requires measures to disrupt the blood-brain barrier, which can vary from prior induction of experimental autoimmune encephalomyelitis with T cells or administration of adjuvants. AQP4-IgG in the CSF is primarily due to ingress of peripherally circulating antibody, but clones of AQP4-IgG–producing B cells are readily isolated from CSF.

AQP4 is a water channel critically involved in mass water transport, and impairment of AQP4 function predisposes to vasogenic edema; this may explain the uncommon but reported occurrence of posterior reversible encephalopathy in patients with NMOSD, believed to be a manifestation of vasogenic edema. AQP4 is capable of "supramolecular aggregation" of

its component heterotetrameric subunits, particularly in optic nerve and spinal cord, where it is highly expressed, and these aggregates provide an antigenic configuration able to bind dense arrays of AQP4 antibody and facilitate binding of complement component 1q (C1q) and complement activation by the classic pathway. AQP4-IgG binding can internalize AQP4 water channels. More importantly, it leads to complement activation and antibody-mediated natural killer cell cytotoxicity, leading to a cascade of downstream effector functions, including chemotaxis of neutrophils and eosinophils and activation of membrane attack complex, which can be demonstrated immunopathologically in recent lesions of NMO. However, some lesions, despite evidence of loss of AQP4 immunoreactivity, do not have immunopathology markers of terminal complement activation and maintain tissue viability; such lesions are associated with clinical recovery. Blocking synthesis of immunoglobulin by targeting B cells (eg, inebilizumab) or trophic factors of plasmablasts (eg, satralizumab), and blocking complement activation with drugs that target C5a generation (eg, eculizumab) are effective strategies for preventing NMO attacks. Plasma exchange is an effective acute treatment for attacks of NMO.

AQP4-expressing non-CNS tissues are relatively but not absolutely spared by this disease. Myalgia may occur coincidentally with attacks of NMOSD and may be accompanied by increases in creatine kinase but rarely by weakness. Muscle biopsy has identified marked loss of immunoreactivity of AQP4 on muscle tissues accompanied by inflammation, similar to findings detected in affected CNS tissues.

The pathogenicity of MOG autoimmunity was recognized from in vivo models of experimental autoimmune encephalomyelitis induced by immunization with MOG; the distribution of affected tissues was primarily determined by major histocompatibility antigens. Brown Norway-genotype rats had a distribution of lesions most reminiscent of NMO. Rodent-derived MOG-IgG is capable of generating prominent demyelination either with or without concomitant T cell–induced experimental autoimmune encephalomyelitis. However, pathogenicity of the human antibody has been difficult to demonstrate in some experimental systems, in part because human MOG-IgG does not recognize rodent MOG. Human MOG lesion pathology in biopsies appears to be similar to acute disseminated encephalomyelitis with overrepresentation of CD4, rather than CD8 cells as seen in MS. Lesions tend to be less necrotic than those associated with AQP4-IgG, as might be expected from the overall better prognosis.

T-cell Activation, Helper T Cell 17 Polarization, B-cell Recognition, and "Upstream" Pathogenesis

The source of the inciting antigen is unknown for either AQP4-associated or MOG-associated NMOSD. Infrequently, patients with AQP4-IgG–associated NMOSD have underlying AQP4-expressing cancers that are suspected of inciting the autoimmune response by "molecular mimicry." However, in the majority of patients with AQP4-IgG–associated NMOSD, the source of the inciting antigen is unknown. Titers of antibody are much greater in the periphery suggesting that this is an "outside-in" disease, but clones of antibody-producing cells are identifiable in the CSF. There is evidence of overexpression of immune cytokines, including those involved in helper T cell 17 (Th17)-mediated disease, for example, interleukin (IL)-6 and IL-17. The pathology of the disease, which includes prominent infiltration with neutrophils and pattern of response to immunotherapy, is also consistent with Th17-facilitated autoimmunity. Recent studies implicate central and peripheral defects in immune tolerance in NMOSD as occurs in other autoimmune disease.

DIAGNOSIS

Characteristic Symptoms and Diagnostic Criteria

NMOSD usually presents as a relapsing central nervous system demyelinating disease with attacks of ON and transverse myelitis. Approximately 5% to 10% of patients have monophasic (nonrelapsing) and up to 3% have a secondary progressive course. The discovery of AQP4-IgG allowed clinicians to identify a broader clinical spectrum of the disease because of the demonstrated specificity of the marker. Other NMOSD syndromes include diencephalic, cerebral, brainstem, and dorsal medulla syndrome (area postrema).

ON in NMOSD typically presents as a severe, acute, painful, visual impairment that can lead to blindness in one or both eyes, either simultaneously or sequentially. Transverse myelitis presents with acute sensory, motor, and sphincter impairments, often severe, associated with a central intramedullary spinal cord lesion extending over three or more contiguous vertebral segments, often referred to as *longitudinally extensive transverse myelitis*, as distinguished from short, generally peripheral spinal cord lesions in MS. Myelitis may be associated with lesions shorter than vertebral segments in approximately 15% of patients and may lead to misdiagnosis of MS, but typically lesions are central in the cord, similar to longitudinally extensive myelitis. Paroxysmal tonic spasms are dystonic spasms that should be distinguished from spasticity repeat in a highly stereotyped fashion. Typically, they are preceded with a sensory "rush," which is rapidly followed by a dystonic posture of one or more limbs, either unilateral or bilateral. This phenomenon is thought to be due to ephaptic transmission of propagating action potentials in demyelinated axons. While they occur in MS, paroxysmal tonic spasms are more common and severe in patients with transverse myelitis due to AQP4-IgG–associated NMOSD and respond to treatment with carbamazepine or oxcarbazepine.

Area postrema syndrome is characterized by unexplained intractable hiccups or nausea or vomiting, generally associated with either paired lesions in the dorsal medulla or myelitis lesions with rostral extension into the dorsal medulla. About 20% of patients present with this syndrome, and 40% will experience it at some stage of their disease, particularly those who are AQP4-IgG seropositive.

Diencephalic syndromes include hypersomnolence, narcolepsy, anorexia, hypothermia, hyponatremia, and behavioral changes associated with a lesion in the thalamus, hypothalamus, or in the walls of the third ventricle. Other cerebral syndromes in NMOSD include hemiparesis, hemisensory loss, encephalopathy, postchiasmal visual loss, and cortical vision loss that are typically associated with large, confluent subcortical, or deep white-matter lesions or lesions that conform to the distribution of long tracts within the brain. Cerebral and diencephalic syndromes are more common in children and in patients with aggressive disease.

Diagnosis of NMOSD relies on clinical, radiographic, and laboratory features. Diagnostic criteria, first proposed by Wingerchuk et al in 1999, was revised in 2006 and, most recently supplanted in 2015 by the International Panel for NMO Diagnosis (Table 73.2). The 2006 revision incorporated AQP4-IgG serology status. In 2015, NMOSD was proposed as the umbrella term for traditional neuromyelitis optica and its more recently recognized brain syndromes; the diagnosis was further stratified in two groups: those seropositive for AQP4-IgG and those who were either seronegative or whose status was unknown. In AQP4-IgG–seropositive individuals, only a single compatible clinical syndrome is necessary (eg, ON or TM), and the diagnosis may be made at first presentation. In AQP4-IgG–seronegative individuals, more than one syndrome in more than one affected location (eg, ON and brainstem) is required and at least one must be a cardinal syndrome (ON, longitudinally extensive transverse myelitis, or area postrema syndrome). Potential mimics of NMOSD should be excluded. A 2017 study found that the application of the 2015 criteria increased the rate diagnosis of NMOSD in clinically suspected cases by 76%, primarily in AQP4-IgG–seropositive cases; however, the specificity of the new diagnostic criteria require further validation.

TABLE 73.2 Neuromyelitis Optica Spectrum Disorder Diagnostic Criteria

Diagnostic Criteria for NMOSD With AQP4-IgG

1. At least one core clinical characteristic
2. Positive test for AQP4-IgG using best available detection method (cell-based assay strongly recommended)
3. Exclusion of alternative diagnoses

Diagnostic Criteria for NMOSD Without AQP4-IgG or NMOSD With Unknown AQP4-IgG Status

1. At least two core clinical characteristics occurring as a result of one or more clinical attacks and meeting all of the following requirements:
   A. At least one core clinical characteristic must be optic neuritis, acute myelitis with LETM, or area postrema syndrome.
   B. Dissemination in space (two or more different core clinical characteristics)
   C. Fulfillment of additional MRI requirements, as applicable
2. Negative tests for AQP4-IgG using best available detection method, or testing unavailable
3. Exclusion of alternative diagnoses

Core Clinical Characteristics

1. Optic neuritis
2. Acute myelitis
3. Area postrema syndrome: episode of otherwise unexplained hiccups or nausea and vomiting
4. Acute brainstem syndrome
5. Symptomatic narcolepsy or acute diencephalic clinical syndrome with NMOSD-typical diencephalic
6. Symptomatic cerebral syndrome with NMOSD-typical brain lesions

Additional MRI Requirements for NMOSD Without AQP4-IgG and NMOSD With Unknown AQP4-IgG Status

1. Acute optic neuritis: requires brain MRI showing (1) normal findings or only nonspecific white matter lesions OR (2) optic nerve MRI with T2-hyperintense lesion or T1-weighted gadolinium-enhancing lesion extending over >1/2 optic nerve length or involving optic chiasm
2. Acute myelitis: requires associated intramedullary MRI lesion extending over 3 contiguous segments (LETM) or more than or equal to three contiguous segments of focal spinal cord atrophy in patients with prior history compatible with acute myelitis
3. Area postrema syndrome: requires associated dorsal medulla/area postrema lesions
4. Acute brainstem syndrome: requires associated periependymal brainstem lesions AQP4-IgG

Abbreviations: AQP4-IgG, aquaporin-4 immunoglobulin G; LETM, longitudinally extensive transverse myelitis; MRI, magnetic resonance imaging; NMOSD, neuromyelitis optica spectrum disorder.

Serologic Testing and Cerebrospinal Fluid

AQP4-IgG is a highly sensitive (73%) and specific (91%) biomarker and is detected in sera of most NMOSD patients (68%-91%). Detection of AQP4-IgG is now an integral aspect of establishing the diagnosis, although the diagnosis can be made on clinical grounds. Cell-based assays, in which the substrate for antibody detection is recombinant antigen expressed in a cell line in native conformation, are the preferred methodology, although other assays have acceptable, although imperfect specificity, which depend on the clinical probability of the diagnosis. A meta-analysis found the approximate sensitivity for the cell-based assay, the tissue-based assay, and the enzyme-linked immunosorbent assay test to be 0.76 (95% CI, 0.67-0.82), 0.59 (95% CI, 0.50-0.67), and 0.65 (95% CI, 0.53-0.75), respectively, whereas the specificity of the cell-based assay was 0.99 (95% CI, 0.97-0.99), tissue-based assay 0.98 (95% CI, 0.97-0.99), and enzyme-linked immunosorbent assay 0.97 (95% CI, 0.96-0.99).

CSF examination is not part of the latest revised diagnostic criteria. However, CSF pleocytosis of more than or equal to 50 WBC/mm^3 or more than or equal to 5 neutrophils/mm^3, usually detected during an acute attack, and absence of oligoclonal bands support diagnosis of NMOSD, whereas unique oligoclonal bands are present in 80% to 90% of patients with MS. Mild pleocytosis less than 50 WBC/mm^3 with lymphocyte predominance is nonspecific and can be seen in either condition. The CSF glial fibrillary acidic protein, a marker for oligodendrocyte injury, is an additional diagnostic biomarker in NMOSD, which increases by several orders of magnitude during relapses and the degree of elevation may predict level of impairment at 6 months follow-up.

In AQP4-IgG–seronegative patients with NMOSD, testing for MOG-IgG is valuable and this autoantibody may be present in up to 50%.

Red Flags, Comorbid Conditions, and Differential Diagnosis

The 2015 International Panel for NMO Diagnosis diagnostic criteria describe a number of caveats to be considered when evaluating a patient with NMOSD. Clinical and radiographic "red flags" to consider at diagnosis of NMOSD are summarized in Table 73.3.

NMOSD can coexist with other autoimmune disorders such as myasthenia gravis, systemic lupus erythematosus, Sjögren syndrome, undifferentiated connective thyroid disease, and pernicious anemia. An AQP4-IgG or MOG-IgG NMOSD may coexist with anti–*N*-methyl-D-aspartate–receptor encephalitis. A CV2/collapsin response mediator 5 antibody (CV2/CRMP5 IgG) mediated disease may be associated with ON or TM and mimicking NMOSD. However, distinguishing NMOSD from other inflammatory, demyelinating, infectious, metabolic, and neoplastic process can be challenging. The differential diagnosis of NMOSD is wide

TABLE 73.3 "Red Flags" in Diagnosis of NMOSD

Red Flags	Comments
Clinical	
Progressive course	More common in MS
Hyperacute onset	Suggestive of spinal cord infarct
Oligoclonal bands in CSF	More typical of MS but detected in up to 20% of cases of NMOSD
Systemic illness including HIV, sarcoid, cancer, syphilis	Potential mimics of NMOSD
Radiographic	
Short spinal cord lesions	More typical of MS
Peripheral spinal cord lesions	More typical of MS
Periventricular lesion in brain, especially oriented perpendicular to ventricles	More typical of MS
Persistently gadolinium enhancement (>3 mo)	Suggestive of neoplasm or infection

Abbreviations: CSF, cerebrospinal fluid; HIV, human immunodeficiency virus; MS, multiple sclerosis; NMOSD, neuromyelitis optica spectrum disorder.

and depends on whether the presentation is suggestive of ON, TM, or both (**Table 73.4**). The MOG-IgG NMOSD and MS are the main differential diagnoses, although other entities listed in **Table 73.4** should be considered, particularly acute disseminated encephalomyelitis, neurosarcoidosis, and paraneoplastic disorders.

Neuromyelitis Optica Spectrum Disorder Versus Multiple Sclerosis

Distinguishing NMOSD from MS has important prognostic and therapeutic implications because a number of MS disease-modifying treatments are ineffective and possibly harmful to patients with NMOSD. Relative to NMOSD, patients with MS are older at onset, more often women, and non-Caucasian, rarely developing a secondary progressive course. Attacks of NMOSD are more severe and more often associated with incomplete recovery. An MRI brain is often normal at first diagnosis in NMOSD, whereas it rarely is in MS. Attacks of myelitis are associated with longitudinally extensive spine MRI lesions in NMOSD but rarely in MS. Lesions in ON in AQP4-IgG–seropositive NMOSD are more often long and associated with posterior optic nerve or chiasm involvement than are lesions in MS-associated ON. Other lesions in the brain that are distinctive are longitudinally extensive corpus callosum lesions and hypothalamic and thalamic lesions, often bilateral. Optical coherence tomography shows greater thinning of retinal nerve fiber layer than seen in MS, reflecting greater axonal injury. The CSF unique oligoclonal bands are detected in less than 20% of patients with NMOSD, whereas they are found in over 85% of patients with MS.

AQP4-IgG– Versus MOG-IgG–Associated NMOSD

MOG-IgG–associated disease can present with clinical and radiologic features similar to NMOSD and MS. Table 73.5 summarizes key clinical and radiologic differences. Compared to patients with AQP4-IgG, patients who are seropositive for MOG-IgG have a higher frequency of bilateral simultaneous ON, acute disseminated encephalomyelitis syndrome, or encephalitis with seizures and

TABLE 73.4 Differential Diagnosis of NMOSD

Combinations of Optic Neuritis, Myelitis, and/or Brain Disease
Multiple sclerosis
Acute disseminated encephalomyelitis
Neurosarcoidosis
Neuro-Behçets disease
Paraneoplastic disease (especially associated with CRMP5)
Adult-onset Alexander disease (long segments of spinal cord atrophy with enhancing brainstem lesions)
Optic Neuritis
CRION
Leber optic neuropathy
Optic nerve tumor
Brain Lesions
Wernicke encephalopathy
Marchiafava-Bignami disease (corpus callosum lesions and diffuse white matter lesions)
Central nervous system lymphoma
Primary angiitis of the central nervous system
Rhombencephalitis
Gliomatosis cerebri
X-linked adrenoleukodystrophy (enhancing lesions in splenium of corpus callosum and deep white matter)
Transverse Myelitis
Spinal cord infarction
Spinal cord arteriovenous fistula
Idiopathic transverse myelitis
Infectious transverse myelitis (varicella zoster, enterovirus, flavivirus, syphilis, tuberculosis)

Abbreviations: CRION, chronic relapsing inflammatory optic neuropathy; CRMP5, collapsin response mediator protein 5; NMOSD, neuromyelitis optica spectrum disorder.

TABLE 73.5 Clinical and Radiologic Features in AQP4-IgG– Versus MOG-IgG–associated NMOSD

	AQP4-IgG NMOSD	MOG IgG-NMOSD
Bilateral simultaneous optic neuritis	+	++
Optic disc edema or papillitis	+	+++
Acute spinal cord syndrome	+	++
ADEM syndrome	+	++
Encephalitis with seizure syndrome	Not reported	+
Multifocal cortical and subcortical radiographic lesions (**Fig. 73.2**)	Not reported	++
Gadolinium enhancing spinal cord lesion (**Fig. 73.4**)	+++	+
Linear nonenhancing spinal cord lesion on sagittal images (**Figs. 73.4 and 73.5**)	+	+++
Monophasic (nonrelapsing) course	+	++

Abbreviations: +, occurs but <10%; ++, well described but <50% of cases; +++, occurs in the majority of cases; ADEM, acute disseminated encephalomyelitis; AQP4-IgG, aquaporin-4 immunoglobulin G; MOG-IgG, myelin oligodendrocyte glycoprotein IgG; NMOSD, neuromyelitis optica spectrum disorder.

FIGURE 73.2 Magnetic resonance imaging brain, T2/fluid-attenuated inversion recovery sequences. **A:** Aquaporin-4 immunoglobulin G–positive neuromyelitis optica spectrum disorder showing isolated lesion in the hypothalamus; usually magnetic resonance imaging of the brain is normal. **B:** Myelin oligodendrocyte glycoprotein immunoglobulin G–positive neuromyelitis optica spectrum disorder showing multifocal large hyperintensities. **C:** Multiple sclerosis showing multiple small periventricular, subcortical, and juxtacortical hyperintensities.

multifocal cortical and subcortical lesions (**Fig. 73.2**) and may not satisfy criteria for NMOSD. The acute myelitis lesions associated with MOG-IgG tend to be long, similar to those associated with AQP4-IgG, but less extensive and demonstrate less and occasionally no enhancement (**Figs. 73.3** and **73.4**) and occasionally have a long linear ("string sign") appearance on sagittal T2 sequences of the spinal cord (**Fig. 73.5**). Up to 50% of those who are MOG-IgG seropositive may not relapse, especially patients who revert to seronegative. Therefore, and given the relatively better outcome of attacks in MOG-IgG–seropositive patients, observation only after a first attack may be appropriate in those with MOG-IgG–associated disease.

FIGURE 73.3 Magnetic resonance imaging cervical spine, sagittal (**top tier**) and axial T2 (**bottom tier**) sequences showing transverse myelitis in patients with neuromyelitis optica spectrum disorder. **A:** Aquaporin-4 immunoglobulin G positive, showing swollen large central spinal cord lesion. **B:** Myelin oligodendrocyte glycoprotein immunoglobulin G positive showing less extensive central lesion affecting gray matter. **C:** Multiple sclerosis with discrete short lesion extending over less than one vertebral segment eccentrically located in the lateral column.

FIGURE 73.4 Magnetic resonance imaging cervical spine, sagittal (**top tier**) and axial (**bottom tier**) sequences following gadolinium administration, showing transverse myelitis in patients with neuromyelitis optica spectrum disorder. **A:** Aquaporin-4 immunoglobulin G positive with ring enhancement that is moderately extensive. **B:** Myelin oligodendrocyte glycoprotein immunoglobulin G positive, with much less extensive enhancement confined to periphery of the spinal cord, primarily anteriorly.

FIGURE 73.5 Magnetic resonance imaging cervical spine, sagittal T2 sequences, showing "string sign" in a patient with myelitis due to myelin oligodendrocyte glycoprotein immunoglobulin G–associated neuromyelitis optica spectrum disorder.

MANAGEMENT

Management is directed to treatment for acute attacks and maintenance treatment to prevent such attacks and accompanying accumulation of incremental disability. Maintenance treatment for AQP4-IgG NMOSD should be instituted at time of diagnosis in all patients due to the high risk of disabling relapses. Until recently, NMOSD was often managed with treatments directed to MS with which NMOSD was often confused. Several MS treatments appear to be either ineffective (glatiramer acetate), or possibly deleterious to patients with NMOSD (interferon-β, natalizumab, fingolimod, and alemtuzumab). Hence, an accurate diagnosis and distinction from MS is essential to successful treatment of patients with NMOSD. In 2019, the results of four phase 3 clinical trials were announced of three agents in treating NMOSD, and as of the writing of this chapter, one, eculizumab, has been approved by the U.S. Food and Drug Administration for treatment of AQP4-IgG–seropositive NMOSD.

Acute Attacks

NMOSD exacerbations or acute attacks are usually treated with intravenous methylprednisolone (IVMP) 1,000 mg daily, for 3 to 7 consecutive days. Corticosteroids inhibit the inflammation cascade by suppressing the production of inflammatory cytokines, T-cell activation, and decreasing permeability of the blood-brain barrier.

Because NMOSD relapses tend to be severe and not respond well to corticosteroids, plasmapheresis (PLEX) is used as a rescue or possibly an adjunctive treatment. PLEX is usually administered

as five to seven exchanges of approximately 1.5 plasma volumes every other day. PLEX eliminates pathogenic plasma factors including cytokines, autoantibodies, and complement components. PLEX treatment results in functional improvement in up to 40% of patients with CNS demyelinating disorders, including NMOSD, who failed corticosteroids during a relapse LEVEL 1.[1] Treatment with IVMP immediately followed by PLEX may result in improved recovery compared to IVMP alone. Better outcomes were reported in patients who received PLEX and were on concomitant treatment with long-term immunosuppressive therapy for NMOSD. Another large retrospective study reported better outcomes of myelitis in patients who were treated with PLEX as primary treatment rather than corticosteroids.

The efficacy of PLEX in NMOSD is not seen exclusively in those who are AQP4-IgG seropositive. Nevertheless, it is important to remember that the only randomized controlled trial experience supporting PLEX efficacy in NMOSD is based on outcomes of a controlled trial of patients with severe CNS demyelinating disease, which included patients with NMOSD and a variety of other acute CNS demyelinating syndromes and by several retrospective studies. A dedicated randomized NMOSD clinical trial of PLEX has not yet been undertaken. Intravenous immunoglobulin, which is effective in a variety of immune-mediated neurologically conditions, has been reported to be somewhat efficacious in patients who failed to respond to IVMP with or without PLEX. Intravenous cyclophosphamide has also been used in a small number of patients as a rescue therapy for attacks of NMOSD longitudinally extensive transverse myelitis refractory to IVMP, PLEX, and intravenous immunoglobulin.

Maintenance Therapy for Neuromyelitis Optica Spectrum Disorder

A number of immunotherapies (Table 73.6), supported mainly by retrospective and observational data, have until the writing of this chapter been the mainstay of treatment of NMOSD. Rituximab, an anti-CD20 monoclonal antibody, administered alone or azathioprine (AZA) or mycophenolate mofetil (MMF) combined with prednisone for 4 to 6 months is considered first-line treatment. Rituximab treated patients had no relapses versus 37% in placebo controlled multicenter study LEVEL 1.[2] Inebilizumab, a CD19 monoclonal antibody, was approved in June, 2020 (United States) to help reduce risk of relapses and disability in NMOSD. Inebilizumab targets a broader spectrum of B cells than rituximab, including plasmablasts and some plasma cells. When inebilizumab was compared to placebo 12% vs. 39% experienced relapses in a phase 3 clinical trial LEVEL 1.[3] Common adverse events are similar to those of rituximab, another B cell depleting agent. Inebilizumab became the second regulator-approved treatment for AQP4-IgG seropositive NMOSD in June, 2020. Alternative maintenance preventative treatments include AZA, mycophenolate mofetil, cyclophosphamide, and methotrexate.

Rituximab was more effective than AZA treatment in a randomized clinical trial and was further established to be effective compared to placebo LEVEL 1.[2] Chen et al found both MMF and AZA to be equally effective in reducing relapse risk, but MMF was associated with fewer or milder adverse events than AZA in patients with NMOSD.

Eculizumab, a C5 complement inhibitor, became the first United States regulator-approved immunotherapy for prevention of attacks in AQP4-IgG–seropositive NMOSD in June 2019 LEVEL 1.[4] It reduced the risk of the first NMOSD relapse following randomization by greater than 90%. Eculizumab predisposes to meningococcal sepsis, but this complication can be substantially prevented by immunization to meningococcus, both with standard conjugate and group B meningococcus vaccinations. Given its recent regulatory approval, eculizumab will likely become widely used particularly for those failing other treatments but considering the lack of long-term efficacy and safety and its high cost, its role in treating NMOSD remains to be established.

Interleukin 6 (IL-6) inhibitors have proven to be effective and safe as an attack prevention strategy for NMOSD. The IL-6

TABLE 73.6 Immunotherapy for Neuromyelitis Optica Spectrum Disorder

Immunotherapy	Dosage	Mechanism	Classification	Common Adverse Events
Rituximab	Two doses 1,000 mg IV in 2 wk apart and repeat every 6 mo	Anti-CD20 monoclonal antibody; B-cell depletion	First line	Infections, leukopenia, hepatotoxicity, reactivation hepatitis B, PML
Azathioprine	2.5-3 mg/kg/d oral	Thiopurine antagonist of endogenous purines; interferes with lymphocyte proliferation	First line	Liver toxicity, leukopenia, recurrent infections, nausea, diarrhea, rash, increased risk of lymphoma
Mycophenolate mofetil	500 mg oral twice a day for 2 wk, then 1,000 mg twice a day thereafter	Inhibitor of inosine monophosphate dehydrogenase, interferes with lymphocyte proliferation	First line	Photosensitivity, leukopenia, infections, headache, abdominal pain, constipation, congenital malformations
Eculizumab	900 mg IV once a week for 4 wk, 1,200 mg IV on week 5, then 1,200 mg IV every 2 wk thereafter	C5 complement inhibitor	Recently approved	Hypertension, headache, fever, diarrhea, nausea, leukopenia, anemia, infections especially meningococcus
Methotrexate	7.5 mg oral or IV weekly, then titrate up weekly up to 22-50 mg weekly	Folic acid antagonist	Second line	Pneumonitis, nausea, diarrhea, cytopenia, hepatotoxicity
